Doktorurkunde ausgehändigt am:

Erklärung

Hiermit erkläre ich an Eides statt, dass ich die Dissertation "Pharmacological targets of β_2 -agonists in β_{2ABC} -receptor deficient mice" selbständig angefertigt und keine anderen als die von mir angegebenen Quellen und Hilfsmittel benutzt habe.

Ich erkläre außerdem, dass diese Dissertation weder in gleicher oder anderer Form bereits in einem anderen Prüfungsverfahren vorgelegen hat.

Ich habe früher außer den mit dem Zulassungsgesuch urkundlich vorgelegten Graden keine weiteren akademischen Grade erworben oder zu erwerben versucht.

I. Summary / Zusammenfassung

Clonidine is an agonist at α_2 -adrenergic receptors that mediate a wide variety of the physiological responses to epinephrine and norepinephrine, such as inhibition of neurotransmitter release as well as sedation and analgesia. As with other therapeutically used α_2 -agonists such as moxonidine and rilmenidine, clonidine possesses an imidazoline structure and is believed to lower blood pressure not only via central and peripheral α_2 -receptors, but perhaps even more so by acting on central “imidazoline I_1 receptors” in the brain stem. The molecular structure of these hypothetical “imidazoline I_1 receptors” has not yet been identified. In order to test whether ligands with an imidazoline structure elicit pharmacological effects via α_2 -adrenergic receptors or via “imidazoline receptors”, mice were generated with a targeted deletion of all three α_2 -adrenergic receptor subtypes (α_{2ABC} -KO). These α_{2ABC} -KO mice were an ideal model in which to examine the pharmacological effects of the centrally acting antihypertensives clonidine, moxonidine and rilmenidine in the absence of α_2 -adrenergic receptors. As expected, sedative and analgesic actions of clonidine were completely absent in α_{2ABC} -KO mice, confirming the sole role of α_2 -receptors in these properties of clonidine. Clonidine significantly lowered heart rate in anesthetized α_{2ABC} -KO and wild-type mice by up to 150 beats/min. A similar bradycardic effect of clonidine was observed in isolated spontaneously beating right atria from α_{2ABC} -KO mice. After treatment with the specific I_f inhibitor ZD 7288, clonidine was no longer able to lower spontaneous beating frequency, suggesting a common site of action. Furthermore, in HEK293 cells stably transfected with HCN2 and HCN4, it could be shown that clonidine inhibits the I_f current via blockade of pacemaker channels with similar affinity as in isolated α_{2ABC} -KO and wild-type atria. This inhibition was demonstrated again in isolated sinoatrial node (SAN) cells from α_{2ABC} -KO mice and was identical in potency and efficacy to clonidine inhibition observed in isolated wild-type SAN cells, confirming that inhibition of atrial HCN channels constitutes the α_2 -independent bradycardic action of clonidine. Direct inhibition of cardiac HCN pacemaker channels contributes to the bradycardic effects of clonidine in gene-targeted mice. Thus clonidine-like drugs represent novel structures for future HCN channel inhibitors.

α_2 -adrenerge Rezeptoren vermitteln die vielfältigen Wirkungen der endogenen Catecholamine Noradrenalin und Adrenalin, darunter auch eine Hemmung der Noradrenalin-Freisetzung sowie Sedierung und Analgesie. Clonidin und die ebenfalls therapeutisch eingesetzten α_2 -Agonisten Moxonidin und Rilmenidin besitzen eine Imidazolin-Teilstruktur. Es wird zur Zeit diskutiert, ob die hypotensive Wirkung dieser Arzneimittel nicht nur auf zentrale und periphere α_2 -Rezeptoren zurückzuführen ist, sondern auch auf sogenannte "I_f Imidazolin-Rezeptoren" in der ventrolateralen Medulla. Bis heute ist die molekulare Struktur dieser hypothetischen Rezeptoren nicht bekannt. Um diese Imidazolin-Hypothese zu überprüfen wurden Mäuse mit einer gezielten Deletion in allen drei α_2 -Rezeptor Genen generiert (α_{2ABC} -KO). Dieses Mausmodell eignete sich hervorragend, um die pharmakologische Wirkung von den zentral-wirksamen Antihypertensiva Clonidin, Moxonidin und Rilmenidin in der völligen Abwesenheit von α_2 -Rezeptoren zu untersuchen. Wie erwartet fehlten die sedativen und analgetischen Wirkungen des Clonidins bei α_{2ABC} -KO Mäusen, wodurch die alleinige Beteiligung von α_2 -Rezeptoren an diesen Eigenschaften des Clonidins bestätigt wurde. Bei anästhesierten α_{2ABC} -KO und Wildtyp-Mäusen zeigte Clonidin eine signifikante Senkung der basalen Herzfrequenz in beiden Genotypen von bis zu 150 Schlägen/min. In ähnlicher Weise setzte Clonidin in isolierten, spontan schlagenden rechten Vorhöfen von α_{2ABC} -KO die Schlagfrequenz herab. Nach Vorbehandlung der Vorhöfe mit dem spezifischen I_f Inhibitor ZD 7288 fand keine weitere Senkung der Schlagfrequenz durch Clonidin mehr statt, was auf einen gemeinsamen Wirkort der beiden Substanzen hindeutete. In stabil transfizierten HEK293 Zellen zeigte Clonidin eine Inhibition des I_f Stromes durch Blockade von HCN2- und HCN4-Kanälen mit ähnlicher Potenz wie in den isolierten Vorhöfen. Ebenfalls in isolierten Sinusknoten (SAN) Zellen von α_{2ABC} -KO und Wildtyp-Mäusen inhibierte Clonidin den I_f Strom mit gleicher Potenz. Diese Befunde bestätigen, dass die Blockade von atrialen HCN-Kanälen den Mechanismus der α_2 -unabhängigen, Clonidin-induzierten Bradykardie darstellt. Die direkte Hemmung von kardialen HCN-Schrittmacher-Kanälen trägt wesentlich zur bradykarden Wirkung von Clonidin bei transgenen Mäusen bei. Clonidin-Derivate bilden somit die Basis für die Entwicklung neuer HCN-Kanal-Inhibitoren.

II. Introduction

1. Autonomic nervous system

Although this project examined the effects of α_2 -adrenergic agonists, their pharmacological targets are by no means exclusively α_2 -receptors. While α_2 -mediated effects predominate, it was possible – with the aid of mice deficient in all three α_2 -receptor subtypes – to identify an additional target of one α_2 -agonist, clonidine. Therefore, it is appropriate to begin with a broad overview of the nervous system, and then narrow the focus to the level of α_2 -adrenergic receptors in order to better understand the context in which they function.

1.1. Nervous system classification

The nervous system of vertebrate animals can be classified either according to its localization or to its function in the body (figure 1). Anatomically, the nervous system can be divided into a central and a peripheral component. The central nervous system (CNS) contains the brain and spinal cord; the peripheral nervous system (PNS) encompasses the afferent (sensory) and efferent (motor) neurons, transmitting information received from sensory receptors to the central nervous system, as well as coordinating impulses received from the central nervous system and relaying them to effector organs in the periphery.

On a functional level, the peripheral nervous system can be divided into a voluntary, or sensory-somatic, nervous system, as well as an involuntary, or autonomic, nervous system. Both somatic and autonomic nervous systems communicate with the central nervous system via sensory and motor neurons. However, the somatic nervous system is responsible for conveying information received from the external environment to the CNS and responding to the external stimulus, while the autonomic nervous system serves as a regulator of the body's internal environment and is crucial for maintaining life-sustaining bodily functions as well as for adaptation to changing external influences. The autonomic nervous system can be further subdivided into a parasympathetic (1.1.1.) and a sympathetic (1.1.2.) nervous system.

Fig. 1: Scheme depicting the vertebrate nervous system. *The interrelation of somatic and autonomic nervous systems, as well as the complex interplay of the sympathetic and parasympathicus within the autonomic nervous system, facilitates the tremendous capabilities of the organism to perceive and respond to an ever-changing external and internal milieu.*

1.1.1. Parasympathetic nervous system

The parasympathetic nervous system is responsible for maintaining the organism in the resting state and, upon stimulation, promotes digestion, lowers heart rate and blood pressure, and upholds the tonus of sphincter muscles of the bladder and bowel. In contrast to the somatic nervous system which only requires one neuron as a link between central and peripheral nervous systems, the parasympathetic nervous system employs a preganglionic neuron originating from either one of the cranial nerves III, VII, IX or X or from the sacral region of the spinal cord in the central nervous system (Hoffman and Taylor, 2001). This neuron synapses with a postganglionic neuron at a ganglion near or in the target organ in the peripheral nervous system. Acetylcholine serves as the neurotransmitter at all preganglionic as well as postganglionic neurons and modulates the parasympathetic nervous system via interactions with muscarinic receptors (M_1 - M_5) at parasympathetic synapses and with nicotinic receptors in the ganglia and at neuromuscular junctions (Dale, 1914; Bonner, 1989).

1.1.2. Sympathetic nervous system

The sympathetic nervous system plays an opposing role to that of the parasympathetic nervous system (1.1.1.). Sympathetic stimulation prepares the body for “fight or flight” by redirecting the blood flow away from the gastrointestinal tract and instead to the skeletal muscles, brain and heart. In addition, heart rate and blood pressure increase, and the trachea and bronchi dilate, further allowing the body to better cope with the stressful situation. Like the parasympathetic nervous system, the sympathetic nervous system utilizes a preganglionic as well as a postganglionic neuron to relay information from the central nervous system to the periphery. While acetylcholine is the neurotransmitter at the sympathetic as well as parasympathetic ganglia, norepinephrine (noradrenaline) is unique to the sympathetic nervous system, where it serves as the postganglionic neurotransmitter at the effector organ. In addition, sympathetic stimulation results in a much more generalized signal than parasympathetic stimulation because one preganglionic neuron (located in the T1 to L2 region of the spinal cord) is able to synapse with any number of postganglionic neurons located along the sympathetic chain (paravertebral ganglia) or with a postganglionic neuron located in an effector organ or in the adrenal medulla (Hoffman and Taylor, 2001). Stimulation of adrenal chromaffin cells releases epinephrine (adrenaline) into the blood stream, further activating adrenergic receptors throughout the body. Adrenergic receptors are discussed in detail in chapter 2.

1.2. Regulation of blood pressure and heart rate

Although adrenergic regulation of the cardiovascular system is discussed later in the Introduction (2.3.1.), the regulation of blood pressure and heart rate is far more complex and requires both parasympathetic and sympathetic input. The heart rate is influenced by the nervous system; however, the frequency of the beating heart is generated within the heart itself, allowing the heart to beat autonomously. Cardiac pacemaker (HCN) channels are crucial to the spontaneous generation of the beating impulse and will be discussed in depth here (1.2.2.). During this project, the HCN channel was identified as a pharmacological target of the α_2 -agonist clonidine.

1.2.1. Blood pressure

Cardiovascular tone is regulated on both a short-term and on a long-term basis through a number of reflex pathways. Afferent pathways relay information from pressor receptors (baroreceptors) in both arterial walls and the heart. The body is able to quickly respond to deviations in blood pressure from a given norm (“set point”) by means of arterial baroreceptors located on the aortic arch and the carotid sinus that register stretch (changes in vessel diameter). Action potentials are generated according to the degree of stretch, and these impulses are relayed from the arterial baroreceptors to the central nervous system where they terminate in the nucleus of the tractus solitarius (NTS). Stimulation of this region in the brain stem elicits a bradycardic vagal response in no more than 0.5 s (Levick, 1998). Baroreceptor activation not only exerts a parasympathomimetic effect; the activated NTS also represses sympathetic tone, with both effects leading to a rapid decrease in heart rate, contractility and therefore cardiac output. As a result, blood pressure decreases. In contrast, an increase in blood pressure occurs indirectly and somewhat more slowly (after circa 1.5 s), as the unstimulated baroreceptor and consequent decrease in vagal activity no longer inhibit sympathetic tone (Levick, 1998).

1.2.2. Heart rate

Although the frequency of the beating heart is modified by both sympathetic and parasympathetic nervous systems in response to external and internal stimuli, the heart beats autonomously. The electrical impulses leading to depolarization of the working myocardium originate within the heart itself, following a hierarchical arrangement of pacemaker regions, each characterized by its own rate of spontaneous depolarization. Under physiological conditions, the sinus node, a small bundle of cells located near the superior vena cava in the back of the right atrium, determines the frequency of the beating heart. The sinus node, also known as the cardiac pacemaker, possesses an unstable resting potential and depolarizes spontaneously approximately once every second in the human heart (Levick, 1998). The depolarization wave passes through the atrium to the ventricle via the atrioventricular node (AV-node), where its velocity is greatly reduced, allowing the atria adequate time to contract before the ventricles are stimulated. Immediately following the AV-node, the electrical impulse enters the ventricle via the His bundle. The long strands of the His bundle are

composed of electrically connected myocytes (also known as Purkinje fibers); these conduct the electrical impulse rapidly along the septum wall and distribute it to the entire ventricle wall, allowing a nearly simultaneous contraction of each ventricle (Levick, 1998). When one of the pacemaker centers is impaired, the next lower center can take over and maintain the beating of the heart, albeit at a lower heart rate. Patients suffering from AV-block generally require a cardiac pacemaker, as the heart rate originating from the His-bundle (approximately 40 beats per minute) in this condition is too low for most activities (Levick, 1998).

Within the sinus node, several different ion currents contribute to the maintenance of pacemaker activity. At the beginning of each new impulse, the membrane potential of the sinus node cell slowly decreases (in humans) from -60 mV to -40 mV (Levick, 1998). This slow decrease, also known as the pacemaker potential, is due in large part to activation of the “pacemaker” or I_f current, characterized by an increased membrane permeability for (mostly) Na^+ ions, thereby making the intracellular membrane potential more positive (Baruscotti and DiFrancesco, 2004). Hyperpolarization activated, cyclic nucleotide-gated cation (HCN) channels provide the basis for this current. To date, four isoforms (HCN1, HCN2, HCN3 and HCN4) have been cloned (Stieber et al., 2004), although HCN4 appears to dominate in the sinoatrial node cells of all mammals studied (Ishii et al., 1999). While the membrane potential becomes less negative, the membrane permeability for K^+ ions decreases as well, prohibiting a repolarization of the cell. As the membrane potential approaches -40mV, voltage-gated L-type Ca^{2+} channels are activated; the inward flow of Ca^{2+} contributes to the last third of the pacemaker potential and “pushes” it over the threshold potential of -40 mV, thereby inducing the next action potential. Ca^{2+} influx prolongs the duration of the action potential. Unlike the action potential of the working myocytes (characterized by a stable membrane potential) and of nerve cells, both sinus node and AV-node cells lack a fast Na^+ current, which is evident by the missing spike at the beginning of the action potential. During the action potential, delayed rectifier K^+ channels activate to slowly induce repolarization. Other ion channels, particularly K^+ channel subtypes, play a lesser contribution to the maintenance of pacemaker activity (for a comprehensive review see Satoh, 2003).

2. Adrenergic system

2.1. Historical aspects of adrenergic receptors

The concept of a “receptor” as the site of drug action emerged slowly during the late nineteenth and early twentieth centuries. The delineation of the paralyzing action of curare by Claude Bernard (1844) aroused the idea of a specific interaction between drug and physiological target (Bennett, 2000). Bernard demonstrated in a curarized frog that, while direct electrical stimulation of a motor neuron failed to elicit a response, stimulation of the muscle nevertheless lead to a contraction. These results were later interpreted by E. Vulpian, suggesting that curare acts on some intermediate zone between nerve and muscle (Vulpian, 1866). However, it was first John Langley whose experiments with agonists and antagonists of the autonomic nervous system and later the neuromuscular junction lead him to correctly deduce the presence of a “receptive substance” (Langley, 1905). Around this time, Paul Ehrlich had envisioned his own “receptor” independent of Langley. In 1885, Ehrlich first described his “side chain theory” of cellular action in his thesis to the University of Leipzig. Ehrlich proposed that a particular toxin could bind specifically to a certain side chain and become neutralized. While this did provide an insightful view of the immune system, it wasn’t until several years later that Ehrlich expanded his theory to include pharmacological substances (Ehrlich, 1900). Ehrlich later went on to introduce the concept of a “chemoreceptor” (Ehrlich, 1914).

Around this time, many researchers became interested in acetylcholine and its nearly identical effects in vivo as those following parasympathetic stimulation (Hunt and Taveau, 1906; Dixon, 1906). However, it wasn’t until 1926 that Loewi and Navratil unequivocally demonstrated that acetylcholine was indeed the neurotransmitter at the autonomic neuromuscular junction (Hoffman and Taylor, 2001). Despite the early report from Cannon and Uridil (1921) that a stimulatory counterpart to acetylcholine was released in postganglionic synapses after sympathetic stimulation of the effector organ, it took another two decades for Ulf von Euler to identify this adrenaline-like neurotransmitter as noradrenaline (Hoffman and Taylor, 2001). Following this discovery, understanding of the adrenergic receptors grew rapidly. In 1948, R. Ahlquist proposed that two subtypes of adrenergic receptors, α and β , mediate the physiological responses of the body to epinephrine and norepinephrine (Black, 1976). This, together with the growing knowledge of the detrimental effects of

epinephrine, led Sir James Black to develop a new class of drugs, the α -blockers, during the early 1960s (Black and Stephenson, 1962). Finally, beginning with the first cloning of an adrenergic receptor (Kobilka et al., 1987), it became gradually clear that all adrenergic receptors represent G protein coupled receptors (chapter 2.4.). Soon thereafter, the human α_2 -subtypes α_{2A} , α_{2B} and α_{2C} were identified and characterized (Kobilka et al., 1987; Weinshank et al., 1990; Regan et al., 1988).

2.2. Receptor subtypes of the adrenergic system

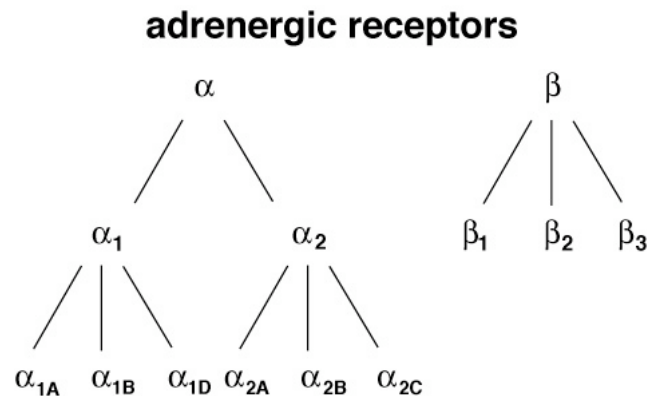

Fig. 2: Adrenergic receptor families. α - and β -adrenergic receptors are categorized into three families α_1 , α_2 and β , which can themselves be divided into three subtypes each.

The sympathetic nervous system imparts its effects on the body via the sympathetic postganglionic neurotransmitter, norepinephrine, and via the endogenous hormone epinephrine, produced by and released from the adrenal glands. While epinephrine conveys a global signal by traveling throughout the body, norepinephrine evokes a much more local signal confined to the area near the presynaptic vesicles from which it was released. The adrenergic system consists of three receptor groups – α_1 -, α_2 - and β -adrenergic receptors (figure 2). Each of these three families can be divided into three receptor subtypes: α_{1A} , α_{1B} , α_{1D} ; α_{2A} , α_{2B} , α_{2C} and β_1 , β_2 and β_3 (Bylund et al., 1994). Although the subtypes of a given family show many similarities, they tend to display characteristic distribution throughout different organs and different tissues. They may also differ in part in their intracellular localization, as in the case of α_2 -adrenergic receptors (chapter 3.2.). Another distinctive feature of the adrenergic receptor subtypes lies in their interactions

with norepinephrine and epinephrine. The two endogenous ligands act on the adrenergic receptor subtypes with different affinities (Hoffman, 2001).

2.3. Role of adrenergic receptors in the sympathetic nervous system

Adrenergic receptors mediate the wide range of physiological responses to norepinephrine and epinephrine in vivo. The three families of adrenergic receptors each contain three receptor subtypes with varying affinities for norepinephrine and epinephrine. This, together with their heterogeneous distribution at both organ as well as cellular levels, facilitates their great pharmacological diversity. Only the adrenergic moderation of the cardiovascular system and metabolism will be discussed here, as these were covered in the scope of this project.

2.3.1. Cardiovascular system

The sympathetic nervous system is best characterized for its role in the modulation of heart rate and blood pressure. Indeed, all three families of adrenergic receptors, α_1 , α_2 and β , represent popular pharmacological targets for antihypertensive drugs. Activation of α_1 -receptors normally elicits a vasoconstrictor response in vascular smooth muscle cells. Although all three α_1 -subtypes have been shown to be present in the endothelium (Miller et al., 1996), α_{1A} and α_{1D} appear to mediate smooth muscle contraction in most arteries in response to α_1 -adrenergic agonists (Guimaraes and Moura, 2001).

Presynaptic α_2 -receptors are located both centrally – α_{2A} - and α_{2C} - subtypes – and peripherally – α_{2A} , α_{2B} and α_{2C} – (Hein et al., 1999; Trendelenburg et al., 2003); as regulators of sympathetic activity, α_2 -autoreceptors indirectly influence blood pressure and heart rate. α_2 -agonists such as clonidine are therefore well-established antihypertensives, although some of these agonists find other uses as well. Endothelial α_2 -receptors promote the release of endothelium-derived relaxing factor (NO) in some blood vessels (Vanhoutte, 2001). Interestingly, the α_{2B} -subtype exhibits a vasoconstriction in the smooth muscle cells of veins and arteries similar to that of the α_1 -subtypes (Link et al., 1996). This effect is clearly demonstrated after iv bolus injection of an α_2 -agonist by an initial increase in blood pressure, which gradually decreases to below baseline level several minutes later. However, this brief hypertension after α_2 -agonist administration is not observed when the drug is taken perorally. α_2 -receptors in the kidney also regulate blood pressure by

influencing the reuptake of salt and water at various locations in the tubule and collecting duct (Wallace et al., 2004).

The family of α -receptors contains three subtypes α_1 , α_2 and α_3 , and both α_1 - and α_2 -subtypes play key roles in sympathetic regulation of the cardiovascular system. Stimulation of α_2 -receptors promotes vasodilation, not only via relaxation of vascular smooth muscle cells, but also indirectly by increasing the activity of endothelial-type nitric oxide synthase (Ferro et al., 2004). Sympathetic activation of α_1 -receptors in the heart elicits positive inotropic and positive chronotropic effects, allowing a greater volume of blood to flow through the body per unit of time, providing more oxygen and a more rapid removal of metabolic wastes. At the same time, α_1 -receptors in the vasculature also contribute to the dilative effect of mixed α_1 - / α_2 -agonists, albeit to a much lesser extent than α_2 -receptors (Chruscinski et al., 1999).

2.3.2. Metabolism

In the resting state, there is little sympathetic intervention into metabolic processes; this is the role of the parasympathetic nervous system. In contrast, activation of the sympathetic nervous system has a tremendous effect on metabolic processes. Glucose is needed to prepare the organism for “fight or flight”, and this sudden increase of available glucose in the bloodstream comes from glycogenolysis of glucose stores largely in the liver and skeletal muscle, followed by glycolysis. Overall energy requirements are elevated, and lipolysis also increases to meet these demands. α_1 -receptor stimulation raises blood glucose levels by promoting glycogenolysis as well as gluconeogenesis. Activation of α_2 -receptors in the β -cells of the pancreas inhibits the Ca^{2+} -induced exocytotic release of insulin via G_o -mediated inhibition of voltage activated Ca^{2+} channels (Wozniak et al., 1995). This acute hyperglycemic response should not be confused with the long-term beneficial effect on blood glucose levels observed with α_2 -agonists such as moxonidine (Jacob et al., 2004). Both α_2 - and α_3 -receptor subtypes stimulate insulin release, while the α_2 -subtype additionally promotes glucose synthesis.

2.4. G protein coupled receptors

The adrenergic receptors belong to the superfamily of G protein coupled receptors (GPCRs). GPCRs, which comprise the majority of all receptors, represent seven-transmembrane proteins with an extracellular N-terminus and

an intracellular C-terminus. Ligand binding occurs typically inside the transmembrane region; only for large ligands such as peptides do extracellular domains play a role in receptor specificity (Krauss, 1997). GPCR ligands include hydrophilic hormones such as gonadotropin, glucagon and parathyroid hormone, as well as most neurotransmitters, including norepinephrine (Dohman et al., 1991). It is therefore not surprising that a great number of pharmaceuticals target GPCRs, either as agonists or antagonists. The great prevalence of GPCRs in mammals is very likely due to the almost innumerable signaling possibilities after receptor activation; this, in turn, is accomplished by the many possible combinations of different subunit isoforms in heterotrimeric G proteins, as well as by the specificity of the receptor / G protein interaction (Neer, 1995).

Upon ligand binding, the activated receptor undergoes a conformational change (Fig. 3, 1st step). A nearby G protein, consisting of an α subunit bound in its inactive state to guanosine diphosphate (GDP) and associated β and γ subunits, binds to the activated receptor, thereby undergoing a conformational change itself. The α subunit, having lost its high affinity to GDP, releases this and quickly binds a molecule of guanosine triphosphate (GTP). GTP binding allows a dissociation of the now active α subunit from the $\beta\gamma$ complex (Fig. 3, 2nd step). At the same time, the active α subunit is released from the receptor complex, leaving the receptor to either react with further G proteins or to become inactive via phosphorylation or by binding of arrestins (Krauss, 1997). Now both α and $\beta\gamma$ subunits are free to interact with effector proteins, leading to different signaling cascades in the cell (Fig. 3, 3rd step).

Effectors are, depending on the G protein subtype, either stimulated or inhibited by the α and $\beta\gamma$ subunits. In the case of G_s proteins which are activated by the family of α_1 -adrenergic receptors, the effector adenylyl cyclase (AC) is stimulated by G_{α_s} , resulting in an increased production of the second messenger cyclic adenosine monophosphate (cAMP). This in turn leads to activation of different signaling pathways in the cell (Ross and Gilman, 1977; Gilman, 1987). On the other hand, G_{α_i} , the α subunit of the inhibitory $G_{i/o}$ protein subfamily stimulated by α_2 -adrenergic receptors, represses the activity of the AC, resulting in a decrease of second messenger cAMP. The $G_{i/o}$ protein $\beta\gamma$ subunits facilitate opening of G protein-activated inwardly rectifying K^+ (GIRK) channels and inhibit N-type Ca^{2+} channels (Bünemann et al., 2001; Starke, 2001). Another G protein subfamily, G_q , activates phospholipase C β , which in turn liberates the second messengers diacylglycerol and inositol-1,4,5

triphosphate; this subfamily binds to β_1 -adrenergic receptors upon activation. Thromboxane receptors may activate the fourth G protein subfamily G_{12} .

Fig. 3: G protein activation cycle as exemplified by the β_2 -adrenergic receptor. Ligand (L) binding to the G_i -coupled receptor induces a conformational change that facilitates binding of a nearby G protein. The G protein similarly undergoes a change in conformation, prompting an exchange of GDP for GTP in the G_α subunit (1.). The active G_α subunit dissociates from the $\beta\gamma$ complex, allowing each to interact with nearby effector molecules (2.). The β_2 -receptor recruits an inhibitory G_i protein whose G_α_i subunit inhibits adenylyl cyclase (AC). The inhibitory $\beta\gamma$ complex interacts with several partners including GIRK (K^+) channels (3.). The intrinsic GTPase capacity of

the G_{β} subunit prompts hydrolysis of GTP to GDP, permitting reassociation of G_{β} and G_{γ} subunits, thereby terminating G protein signaling (4.).

The active G_{β} -GTP subunit is endowed with an intrinsic GTPase activity, ensuring a limited signaling capacity of the G protein. Through hydrolysis of GTP to GDP, the β subunit reacquires its inactive conformation and reassociates with the γ subunit, thus terminating the further interaction with effector proteins (Fig. 3, 4th step). The length of activation time is dependent on the G protein as well as on other regulatory proteins (e.g. RGS proteins). In addition, proteins may either shorten (GTPase activating proteins, GAP) or lengthen (guanine nucleotide exchange factor, GEF) the duration of the G protein signal. Through such modulation, as well as through various combinations of the 20 β , 5 α and 12 γ subunits, a fine-tuned, individual regulation of numerous physiological processes is achieved.

3. β_2 -adrenergic receptors

Negative feedback regulation of sympathetic activity by autoinhibitory β_2 -receptors is crucial in regulating norepinephrine release and maintaining normal levels of plasma catecholamines. Postsynaptic β_2 -receptors are found throughout the body, where they play highly diversified roles (3.4.2.). Often, however, it is difficult to associate a specific physiological process with a certain β_2 -receptor subtype due to high similarities in signaling, (sub)cellular localization and tissue distribution.

3.1. Signal transduction of β_2 -adrenergic receptors

3.1.1. Interaction with inhibitory $G_{i/o}$ proteins

All three β_2 -receptor subtypes belong to the large family of transmembrane G protein coupled receptors and couple mainly to inhibitory $G_{i/o}$ proteins. As previously described in chapter 2.4., dissociation of the heterotrimeric G protein following β_2 -receptor activation and G protein binding allows the free β and γ subunits to interact with a number of downstream partners (Neer, 1995). Although a number of β , α and γ subunit isoforms have been cloned, it has been recently demonstrated, using fluorescence resonance energy transfer (FRET)-labeled $G_{i\beta}$ and $G_{i\gamma}$ subunit isoforms activated by β_2 -receptors in HeLa cells, that not the individual β and γ isoforms but rather the combination of $G_{i\beta}$ and $G_{i\gamma}$ isoforms determines the degree of G protein

activation (Gibson and Gilman, 2006). The G_{β_i} subunit, and perhaps the G_{β_o} subunit as well, inhibits the activity of adenylyl cyclase (AC), thus decreasing the amount of intracellular cyclic AMP (cAMP) and inhibiting cAMP-mediated downstream signaling (Duman and Nestler, 1995). The inhibitory G_{β} subunit both stimulates inward-rectifier K^+ (GIRK) channels as well as inhibits voltage-gated Ca^{2+} channels, resulting in a hyperpolarization of the cell membrane. This dual role is played by $\beta\gamma$ dimers from both G_i and G_o proteins, although each G protein subtype may uniquely contribute to these effects (Duman and Nestler, 1995). In rat sympathetic neurons, G_{β_o} -associated $\beta\gamma$ subunits effected voltage-dependently the norepinephrine-mediated inhibition of N-type Ca^{2+} channels, while the inhibition resulting from $\beta\gamma$ subunits associated with G_{β_i} was voltage-independent (Delmas et al., 1999). This $G_{\beta_{i/o}}\beta\gamma$ -mediated inhibition of Ca^{2+} channels appears fundamental in the autoinhibition of presynaptic α_2 -receptors (Stephens and Mochida, 2005). It has even been demonstrated that free G_{β} subunits inhibit some forms of AC (types I, III and VIII), while contrarily they stimulate other AC forms (II and IV) in vitro (Duman and Nestler, 1995).

Fig. 4: $G_{i/o}$ protein mediated signal transduction of α_2 -adrenergic receptors. The ligand (L)-bound receptor assumes a new conformation preferable to $G_{i/o}$ protein binding, triggering a cascade of events resulting in

either the activation or inhibition of effector proteins (here adenylyl cyclase, GIRK and N-type Ca^{2+} channels) by the liberated $G_{i/o}$ and $G_{\beta\gamma}$ subunits.

3.1.2. Activation of mitogen-activated protein kinase (MAPK) cascade

Aside from the direct downstream signaling pathway of $G_{i/o}$ proteins (inhibition of AC, GIRK channel stimulation, Ca^{2+} channel blockade), G protein stimulation elicits additional downstream effects as well. The ability of free $G_{i/o}$ and $G_{\beta\gamma}$ subunits following β_2 -adrenergic activation to interact with downstream effectors of various growth hormone receptors (tyrosine kinase receptors) is well documented and illustrates again the wide diversity of β_2 -receptors in a multitude of physiological processes including indirect mediation of cell growth and proliferation (Duman and Nestler, 1995). Many circulating hormones such as insulin and other growth factors mediate their physiological effects via activation of complementary growth factor receptors. Hormone binding precipitates dimerization of two adjacent transmembrane receptors, triggering a cascade of phosphorylation of both receptor (autophosphorylation) and of downstream target proteins (Duman and Nestler, 1995). These events lead to the activation of a family of serine / threonine kinases, or MAP-kinases (mitogen-activated protein kinases), which translate the extracellular stimulus into a resulting change in transcription of the target gene(s) and ultimately into changes in cell growth and differentiation (Cano and Mahadevan, 1995). MAP-kinases can be divided into the subfamilies of extracellular signal regulated kinases (ERK1/2 and ERK5), stress-activated protein kinases (SAPK, synonymous with c-jun N-terminus kinases or JNK) and p38 kinase (Lopez-Illasaca, 1998). Each subfamily displays a unique signal transduction pathway, as depicted in figure 5.

Fig. 5: The four subfamilies of MAP-kinases: ERK5, p38, JNK1-3 and ERK1/2. The MAPK cascades can be further grouped into the stress-activated (ERK5, p38 and JNK1-3) or growth hormone-activated (ERK1/2) pathways. Each pathway, though comprised of different members, shares a similar stimulus which is transmitted via successive phosphorylation (and activation) of cascade members down the four-tiered signaling pathway. The original stimulus is then converted into a nuclear signal, prompting the transcription of genes regulating cell growth and differentiation (modified after Seger et al., 2000).

These complex signaling cascades offer many potential partners with which free $G_{i/o}$ and $G_{\beta\gamma}$ subunits can interact. Indeed, though the exact mechanisms are long from being clearly established, there has been much experimental evidence generated for the β_2 -adrenergic-stimulated, $G_{\beta\gamma}$ -mediated activation of Rho (Roberts, 2004), epidermal growth factor (EGF) receptor (Pierce et al., 2001; Cussac et al., 2002), Pyk2 (Della Rocca et al., 1997), Src (Pierce et al., 2000), Shc (Cussac et al., 2002), PLC with subsequent activation of Ras-dependent ERK1/2 (Della Rocca et al., 1997), and MEK (Kribben et al., 1997; Taraviras et al., 2002), to name but a few examples. Another proposed pathway of ERK1/2 activation, documented for both β_{2A} - and β_{2B} -subtypes in certain cell types, is the β_2 -agonist-mediated transactivation of EGF-receptors as shown in figure 6 (Cussac et al., 2002; Daub et al., 1996; Prenzel et al., 1999). This transactivation process was similarly demonstrated in the mouse placenta, and is believed to provide a mechanism for the involvement of the β_{2B} -subtype in vascularization of the placenta during early embryonic development (Philipp et al., 2002c).

Fig. 6: β_2 -adrenoceptor-mediated activation of MAPK cascade. A proposed mechanism of ERK1/2 activation by the β_{2B} -adrenergic receptor via transactivation (modified after Cussac et al., 2002) is depicted above. Following β_2 -agonist binding and subsequent G_i protein activation, $G_{\beta\gamma}$ subunits appear to increase production of arachidonic acid (AA) via stimulation

of phospholipase A_2 (PLA₂). Cytoplasmic lipoxygenase (LOX) and cyclooxygenase (COX) convert AA into metabolites which stimulate matrix metalloproteinases (MMP) to cleave heparin-binding EGF-like growth factor (HB-EGF) from its transmembrane receptor. HB-EGF binds to the EGF receptor, inducing autophosphorylation of the tyrosine kinase receptor and recruiting the adaptor protein Shc, which then interacts with the Grb2-Sos complex. Sos, a guanine nucleotide exchange factor for Ras, activates this, thereby initiating the ERK1/2 MAPK-signaling cascade (Lotti et al., 1996).

3.2. Subtype-specific cellular localization

Despite the high degree of amino acid homology within the transmembrane regions of the three β_2 -adrenergic receptor subtypes, each subtype exhibits a unique pattern of cellular distribution. Characteristic of transmembrane G protein coupled receptors, both β_{2A} - and β_{2B} -subtypes are located primarily at the cell membrane under basal conditions (figure 7). In contrast, the β_{2C} -subtype is found to a large extent in intracellular compartments (endoplasmic reticulum and cis / medial Golgi compartments) in many cell types (Daunt et al., 1997; Saunders and Limbird, 1999). Neither the molecular basis for nor the (possible) significance of this deviant location of the β_{2C} -subtype is known at present, although the growing concept of “microdomains”, in which reaction partners of a signaling cascade may preferentially interact, may offer an attractive explanation (Neer and Clapham, 1988). Indeed, β_{2C} -receptors in PC-12 cells, a neuroendocrine-derived cell line, were observed to be concentrated in the cell membrane of neurite outgrowths, suggesting a cell-type specific targeting of the β_{2C} -subtype in this cell line (Hurt et al., 2000).

Furthermore, all β_2 -subtypes differ in the extent of desensitization and internalization following receptor activation. In transfected CHO cells, β_{2A} - and β_{2B} -receptor subtypes underwent desensitization following 30 minutes exposure to epinephrine, while the β_{2C} -subtype did not (Eason and Liggett, 1992). Differences in the amino acid sequences of the third intracellular loop, a highly heterogeneous region between the subtypes, appeared to dictate the degree of phosphorylation by β -adrenergic receptor kinase (β ARK) and therefore receptor desensitization (Jewell-Motz and Liggett, 1996). Following agonist exposure in transfected HEK293 cells, the β_{2B} - but not β_{2A} -subtype internalized and appeared to be sequestered in the same endosomes as the β_2 -adrenergic receptor, suggesting a common mechanism (Daunt et al., 1997). The authors found evidence of agonist-induced internalization of the β_{2C} -

subtype as well, although internalization of the small percentage of surface α_{2C} -receptors was initially obscured by the high background of intracellular α_{2C} -receptors (Daunt et al., 1997).

Fig. 7: Differences in α_2 -receptor subtype subcellular localization and trafficking. As G protein coupled receptors, all three α_2 -subtypes are located at the cell membrane; however, the α_{2C} -subtype has also been found in intracellular compartments in many cell types. Following receptor activation, the α_{2B} - and to a lesser degree the α_{2C} -subtypes, but not α_{2A} , internalize and are recycled to the plasma membrane.

In polarized cultured Madin-Darby canine kidney II (MDCKII) cells, a similar pattern of α_2 -receptor subtype subcellular localization was observed as described above (Saunders and Limbird, 1999). While all three subtypes were detected nearly exclusively at the basolateral membrane (excluding the intracellular pool of α_{2C} -receptors), the authors observed that only the α_{2A} - and α_{2C} -receptor subtypes were directly delivered to this membrane. In contrast,

the α_{2B} -subtype was randomly delivered to either the basolateral or the apical membrane; merely the short duration of the α_{2B} -receptor on the apical membrane (half-life 0.25-0.5 h) compared to the long half-life (12 h) at the basolateral membrane surface gave the appearance of a true targeting, as was the case with the α_{2A} - and α_{2C} -receptor subtypes. Post-translational receptor modifications, e.g. palmitoylation and glycosylation, have not been found to influence either receptor trafficking or subcellular localization of the α_{2A} -subtype (Saunders and Limbird, 1999), and deletion of the third intracellular loop was likewise without effect on trafficking of the α_{2A} -subtype to the MDCK cell membrane (Keefer et al., 1994).

3.3. Tissue distribution of α_2 -receptor subtypes

As implied by the vast array of physiological processes mediated exclusively or partially by catecholamines, α_2 -adrenergic receptors are widely distributed throughout the entire organism. The role of central presynaptic regulator of norepinephrine release suggests a high density of α_2 -receptors in the brain (figure 8). This is indeed the case; mRNA for α_{2A} -receptors, the predominant presynaptic inhibitor both centrally as well as in the periphery, was located abundantly in the locus ceruleus, but also found in the cerebral cortex, septum, hypothalamus, hippocampus, amygdala and the nucleus tractus solitarius (NTS) and rostral ventrolateral medulla (RVLM) regions of the brain stem in rat brain (Nicholas et al., 1993; Scheinin et al., 1994). The α_{2C} -subtype, playing a subordinate role in presynaptic inhibition, displayed a unique pattern of mRNA expression primarily in cerebral cortex, hippocampus, olfactory bulb and basal ganglia in rat brain (Scheinin et al., 1994). Immunohistochemical studies affirmed the location of the corresponding α_{2A} - and α_{2C} -receptor proteins (Talley et al., 1996; Rosin et al., 1996). In contrast, mRNA for the α_{2B} -subtype in rat brain was found in modest amounts exclusively in the thalamus (Nicholas et al., 1993; Scheinin et al., 1994).

In peripheral tissues, pharmacological and radioligand binding studies have shown a heterogeneous distribution of α_2 -receptor subtypes as well. In contrast to central regulation of norepinephrine release, all three α_2 -receptor subtypes contribute to presynaptic autoinhibition in the periphery, as demonstrated in the atria and vas deferens of α_{2AC} -KO mice (Trendelenburg et al., 2003). The α_{2B} -subtype appears to mediate contraction of vascular smooth muscle cells, as this response to α_2 -agonist stimulation was absent in mice lacking the α_{2B} -subtype (Link et al., 1996). However, there is evidence

that the α_{2A} -subtype may contribute to this effect as well (Philipp et al., 2002a). Platelets contain the α_{2A} -subtype, which was originally cloned from this source (Kobilka et al., 1987). The kidney is also rich in α_2 -receptors. mRNA of the α_{2B} -subtype was concentrated in the kidney (Nicholas et al., 1993), and immunoblotting identified both α_{2A} - and α_{2B} -subtypes in human medullary collecting duct cells (Wallace et al., 2004). While mRNA of all three α_2 -subtypes was detected in the adrenal medulla (Takeda et al., 2001), it has been clearly demonstrated that the α_{2C} -subtype is the sole regulator of epinephrine release from chromaffin cells (Brede et al., 2003). Both α_{2A} - and α_{2C} -subtypes are located in the β -cells of the pancreas and appear to independently support the acute hyperglycemic response to sympathetic activation (Peterhoff et al., 2003). α_2 -receptors have also been found in lung, submandibular and salivary glands (Bylund and Martinez, 1981 and 1980), liver (Lomasney et al., 1990), ileum (Chang et al., 1982), spleen and stomach (Saunders and Limbird, 1999).

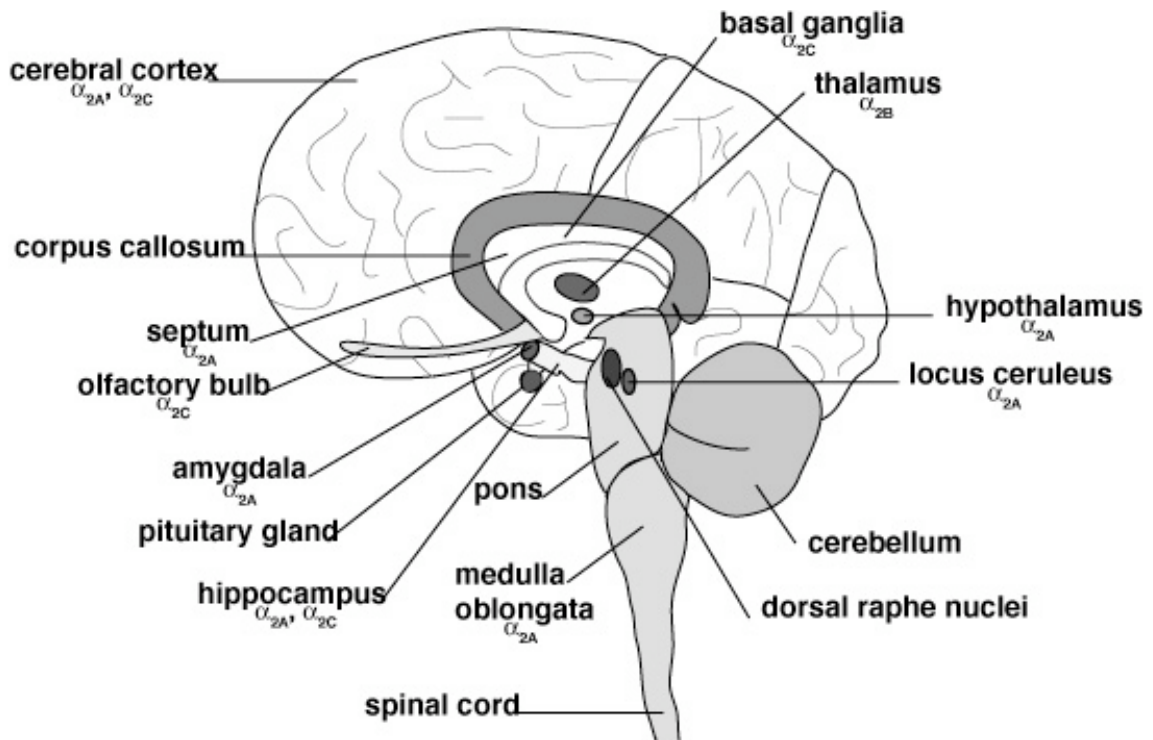

Fig. 8: Sagittal view of the human brain. α_2 -receptors are widely distributed throughout the brain, with α_2 -subtypes often occupying distinct areas. The predominant central autoreceptor, α_{2A} , is found abundantly within the locus ceruleus. Other areas with considerable α_{2A} density include the medulla oblongata, hippocampus, amygdala, hypothalamus, septum and cortex. The

other central autoreceptor, α_{2C} , is located mainly in the cortex, hippocampus, olfactory bulb and basal ganglia, while the α_{2B} -subtype is found only in significant amounts in the thalamus (for references, see text).

3.4. Physiological importance of α_2 -receptors

Presynaptic α_2 -receptors play an essential role in the regulation of sympathetic outflow from adrenergic neurons in both central and peripheral sympathetic nervous systems. Norepinephrine released from neurons activates α_2 -receptors, which in turn via coupling to G_i/G_o proteins leads to a decrease both in further norepinephrine release as well as in the firing frequency of adrenergic neurons (Foote and Aston-Jones, 1995; Starke, 2001).

3.4.1. Presynaptic α_2 -receptors

Presynaptic α_2 -receptors are located throughout the entire central and sympathetic nervous systems on adrenergic neurons. Because they regulate sympathetic activity, α_2 -autoreceptors influence blood pressure and heart rate. α_2 -receptors on presynaptic termini of the ventrolateral medulla, a region in the brainstem encompassing the nucleus reticularis lateralis (NRL), elicit a decrease in sympathetic outflow and consequently hypotension and bradycardia. In its role as the final relay station in the baroreceptor reflex pathway, the NRL is considered to be the major site of action for clonidine and clonidine-like drugs (Szabo, 2002). Likewise, the nucleus tractus solitarius (NTS), the medullar region where afferent baroreceptors terminate, also possesses a high density of α_2 -receptors which elicit the same response as in the NRL. However, the hypotensive effect of presynaptic α_2 -receptors is not limited solely to sympathetic inhibition. In the dorsal vagal nucleus, the origin of parasympathetic fibers of the vagus nerve, α_2 -receptors stimulate parasympathetic outflow and similarly evoke cardiac negative inotropic and bradycardic responses (Wozniak et al., 1995). With the many sites of blockade of central cardiac stimulation, the use and success of clonidine-like drugs as antihypertensive agents is easily understandable. In release experiments with tissue from mice lacking one or two of the three α_2 -receptor subtypes, it could be shown that the α_{2A} -subtype was responsible for approximately 70% of the centrally mediated presynaptic inhibition of norepinephrine release following electrical stimulation of hippocampus sections; the α_{2C} -subtype accounted for the remaining 30% of adrenergic inhibition, while the α_{2B} -subtype appeared to play little or no role either in the

hippocampus or in the periphery (Hein et al., 1999). Several years later, these experiments were repeated with the previously used agonist, UK 14304 (brimonidine), as well as with medetomidine, a full agonist at all three α_2 -receptor subtypes. Medetomidine unveiled the contribution of the α_{2B} -subtype to presynaptic inhibition in peripheral tissues, very similar to that of the α_{2C} -subtype (Trendelenburg et al., 2003). In hippocampus slices, no difference in the inhibition curves obtained with UK 14304 and medetomidine was observed, confirming that the α_{2B} -subtype does not contribute to central inhibition (Trendelenburg et al., 2003).

Catecholamines influence not only physical processes but also behavioral aspects and emotional states as well. The locus ceruleus, an area in the brain stem strongly associated with clinical depression, panic disorder and anxiety, is rich in noradrenergic neurons projecting to the hippocampus, thalamus and cortex (Valentino and Aston-Jones, 1995). Presynaptic α_2 -receptors in the hippocampus suppress norepinephrine release from these neurons, and autoinhibitory overstimulation may contribute to the development of depression, which is according to the widely accepted monoamine theory of depression believed to be linked in part to a norepinephrine depletion in the hippocampus (Delgado and Moreno, 2000). Antidepressants with α_2 -antagonistic action such as mianserin (Dam et al., 1998) and mirtazepine (Guelfi et al., 2001, Leinonen et al., 1999) have been clinically shown to successfully alleviate depressive symptoms, suggesting that α_2 -receptors may indeed be involved in the emergence of the illness.

3.4.2. Postsynaptic α_2 -receptors

In contrast to the antihypertensive use of clonidine, the growing use of clonidine as a pre-, peri-, and/or post-operative adjunct to general anesthetics and analgesics exploits the sedative as well as analgesic properties of the drug. Clonidine given prior to and / or during surgery has generally been found to decrease the amount of anesthetic used perioperatively (Watanabe et al., 2006) and even the amount of analgesic used postoperatively in some cases (Segal et al., 1991; Tripi et al., 2005), though the route of clonidine administration may play a role in its post-operative analgesic efficacy (Mannion et al., 2005). Clonidine is also used to maintain blood pressure stability during endotracheal intubation (Zalunardo et al., 1997). The strong analgesic efficacy of clonidine complements that of opioid analgesics. However, these mechanisms appear to be independent of each other, as mice

lacking the α_{2A} -subtype displayed the expected lack of analgesic response to clonidine yet were not impaired in their reaction to morphine (Özdoğan et al., 2004). With the aid of α_{2A} - and α_{2C} -deficient mice crossed with Flag-tagged α_{2A} -transgenic mice under the control of the dopamine β -hydroxylase promoter, it could be unequivocally demonstrated that an analgesic response to the α_2 -agonist medetomidine failed to return with the reintroduction of α_{2A} -receptors. Dopamine β -hydroxylase, a hallmark of noradrenergic neurons, is restricted to adrenergic neurons. In contrast, the sedative effects of α_2 -agonists returned to α_{2A} - and α_{2C} -deficient mice after crossing them with Flag-tagged α_{2A} -transgenic mice, indicating that presynaptic α_2 -receptors mediate sedation (Röser, 2005). Postsynaptic α_2 -receptors contributing to analgesia occur at both spinal as well as supraspinal loci (Guo et al., 1996; Pertovaara et al., 1991).

Postsynaptic α_2 -receptors modulate hemodynamic responsiveness to adrenergic stimulation. Most notably the α_{2B} -subtype mediates vasoconstriction such as that exhibited by clonidine in arterial vessels (Kiowski et al., 1983, Link et al., 1996). However, depending on the vascular bed, either the α_{2A} - or the α_{2C} -subtype may be involved as well (MacMillan et al., 1996; Philipp et al., 2002a). Uniquely, certain “silent” α_{2C} -receptors seem to be activated upon cooling below 37°C and in HEK293 cells have been found to relocate from an intracellular pool to the cell membrane, where they induce vasoconstriction (Chotani et al., 2000; Jeyaraj et al., 2001). It is interesting that both α_2 -antagonists (phenoxybenzamine) as well as agonists (guanethidine) are therapeutically used to treat the symptoms of Raynaud’s disease, which is characterized by paroxysmal vasospasms of the fingers, and sometimes nose and tongue, often triggered by exposure to cold. α_2 -receptors contribute to the maintenance of blood hemostasis as well. Platelets are endowed with α_2 -receptors which, upon stimulation with endogenous epinephrine and consequent coupling to G_i proteins, inhibit adenylyl cyclase, leading to a decrease in antiaggregatory cAMP and to an increase in the potent platelet activator ADP (adenosine diphosphate), thereby promoting platelet aggregation (Siess, 1989).

Blood glucose homeostasis is maintained in part by postsynaptic α_2 -adrenergic receptors (Nakaki et al., 1981). Sympathetic activation of α_2 -receptors on the β -cells of the pancreas decreases intracellular Ca^{2+} via coupling to inhibitory G proteins (2.4.). Ca^{2+} , however, is necessary for the exocytotic release of insulin from vesicles of the Golgi apparatus. In general

there are two mechanisms of glucose-mediated insulin release. A rise in blood glucose triggers insulin release directly via closure of ATP-sensitive K^+ (K^+_{ATP}) channels by ATP generated from the oxidative metabolism of glucose. ATP is an endogenous regulator of insulin release; closure of K^+_{ATP} channels and subsequent depolarization of the β -cell membrane leads to an increase of intracellular Ca^{2+} which liberates insulin in the aforementioned manner (Mutschler, 1997). In addition, glucose has been found to enhance insulin release independent of K^+_{ATP} channels (Gembal et al., 1992), although the exact mechanism remains unclear. Studies with mice deficient in one or more β_2 -subtypes have revealed that the β_{2A} -subtype is the main regulator of the epinephrine-induced suppression of insulin release via activation of β_2 -receptors; however, the role of the β_{2C} -subtype is not negligible and appears to act independently of cAMP in contrast to the β_{2A} -subtype (Peterhoff et al., 2003). Yet another mechanism of β_2 -mediated hyperglycemia may be the stimulation of glucagon secretion, which was first observed in sheep (Oda et al., 1990).

The involvement of postsynaptic β_2 -receptors in a variety of behaviors, affect disorders and cognitive skills has been proposed. β_2 -receptors have been associated with a number of psychological disorders including post-traumatic stress syndrome, attention deficit hyperactivity disorder (ADHD) and schizophrenia (Perry et al., 1987; Morris et al., 2004; Arnsten et al., 1996; Hornykiewicz, 1982; Lindström, 2000). Several studies using β_{2C} -deficient mice have suggested a contribution of this receptor subtype to startle response and the execution of complex navigation patterns (Sallinen et al., 1998; Bjorklund et al., 1999). Particularly the role of the β_{2C} -subtype in aggressive behavior has been observed. β_{2C} -deficient mice have shown a decrease in attack latency in the isolation-aggression test, whereas mice with a tissue-specific overexpression of the β_{2C} -subtype displayed the opposite behavior (Sallinen et al., 1998). More recently, however, attention has been focused on the β_{2A} -subtype, which was shown in experiments with β_{2A} -deficient mice to stimulate functions in the prefrontal cortex involved in memory and attention (Franowicz et al., 2002). These authors similarly identified the β_{2A} -subtype as the molecular target of guanfacine, an β_2 -agonist used, like clonidine, as a non-stimulant drug in the treatment of ADHD in patients not responding to or not tolerating standard psychostimulant treatment, as well as in patients exhibiting tics either comorbidly with ADHD or alone, as in Tourette's syndrome (Chappell et al., 1995; Hunt et al., 1995; Jimenez-Jimenez and Garcia-Ruiz, 2001; Pliszka, 2003). Finally, there is

much evidence to justify the use of α_2 -agonists, notably clonidine, for the treatment of symptoms resulting from opiate and alcohol withdrawal (Gold et al., 1978). A recent study identified the α_{2A} -subtype as the main pharmacological target of clonidine in the alleviation of opiate withdrawal, as α_{2A} -deficient mice showed 70% fewer naloxone-precipitated jumps than wild-type mice (Özdoğan et al., 2004). Despite the general consensus that the clonidine-mediated attenuation of withdrawal symptoms is dependent on inhibition of the overstimulation of both central and peripheral noradrenergic pathways (Devoto et al., 2002; Delfs et al., 2000; Milanés et al., 2001), the precise involvement of certain α_2 -subtypes and the relative contribution of pre- and / or postsynaptic α_2 -receptors is still not known.

3.5. α_2 -receptor ligands

The catecholamines norepinephrine and epinephrine are the endogenous ligands of α_2 -adrenergic receptors. It is therefore reasonable that other small molecules with a 2-phenylethylamine structure could be potential α_2 -agonists or antagonists. However, the α_2 -agonists commonly used as centrally acting antihypertensives or sedatives do not resemble catecholamines at a first glance. This second class of α_2 -ligand, which finds much wider use than the endogenous catecholamines, represents 2-amino imidazolines. A closer look at the prototypical α_2 / imidazoline agonist clonidine reveals a preferred conformation spatially similar to that of norepinephrine, indicating that the 2-amino imidazoline structure is a potentially potent agonist or also antagonist at the three α_2 -receptor subtypes (Roth and Fenner, 2000).

3.5.1. Catecholamine ligands of α_2 -receptors

Despite the highly diverse physiological roles both between as well as within the α_1 -, α_2 - and β -adrenergic receptor families, the catecholamines norepinephrine and epinephrine serve as the endogenous ligands of all these adrenergic receptors. The 2-phenylethylamine moiety of the model substance norepinephrine permits little variability, and each receptor family displays its own 'preferences' as to which manipulations of the leading structure are tolerated before receptor affinity is lost. The stepwise modification of many residues of the norepinephrine structure has been documented along with the resulting changes in the affinity and activity of the new molecule at the α -receptor (Roth and Fenner, 2000). In contrast, the α_2 -receptor has a more stringent structure-activity relationship; only a substitution of the residues on

the amino group is practicable, and increasing the size of the amino substituent tends to diminish the α -activity while increasing the affinity of the drug to the α -receptor (Hoffman, 2001). The deletion of one of the two aromatic hydroxyl groups of the catecholamine allows the drug to be given perorally without inactivation via 3-O-methylation by catechol-O-methyltransferase (COMT). Together with monoamine oxidase (MAO), COMT is a key enzyme in the metabolism of endogenous catecholamines. Loss of the aromatic hydroxyl group(s) renders the molecule devoid of activity at the α_2 -receptor; however, drugs such as amphetamine and ephedrine act as indirect agonists and derive their pharmacological activity by competing with norepinephrine for uptake into storage vesicles (Roth and Fenner, 2000).

Fig. 9: Structures of norepinephrine and epinephrine as well as of the indirect sympathomimetic drugs amphetamine and ephedrine. The latter two substances do not bind to adrenergic receptors. Instead, they compete with the endogenous neurotransmitter norepinephrine for uptake into storage vesicles, thereby increasing the concentration of norepinephrine at the synapse. The asterisk denotes a stereogenic center.

The α_2 -receptor distinguishes itself from the α_1 -adrenergic receptor in its ability to recognize the stereo conformation of the α -methyl residue; Ruffolo and Waddell observed the highly preferential interaction of the α_2 -receptor with

2S(+)- α -methyldopamine, whereas the α_1 -receptor did not prefer either stereoisomer (Ruffolo and Waddell, 1982). Differences in receptor affinity of norepinephrine and epinephrine exist within the α_2 -family as well; these may, at least partially, account for the unequal contribution of the three α_2 -subtypes to presynaptic inhibition (Bünemann et al., 2001).

3.5.2. Imidazoline and imidazoline-like ligands of α_2 -receptors

The chemical and metabolic instability of the catecholamine derivatives was surely impetus for the development of α -agonists lacking phenolic and catechol structures. Tolazoline was the first fruit of the combination of the catechol phenylethylamine moiety with the imidazole structure of histamine, successfully undertaken by scientists at Ciba in Switzerland in 1939 (Szabo, 2002). Clonidine was first synthesized in 1962 by H. Stähle, a chemist at Boehringer Ingelheim. The compound known as St155 was originally conceived as an improvement on the imidazoline-derived nasal decongestants of the time, such as naphazoline and xylometazoline (Scholz, 2002). Despite the structural relation to these previous α -adrenergic agonists, clonidine distances itself from its 2-arylmethyl imidazoline cousins due to a 2-amino imidazoline structure. Clonidine therefore exists predominantly in the more favorable 2-imino imidazolidine form (figure 10), which allows the protonated base to distribute its positive charge throughout the guanidine moiety (Remko et al., 2006). Another unique feature of clonidine compared to the naphazoline-type nasal decongestants is the sterical hindrance of the ortho-chloro substituents, which likely restrain the clonidine molecule in a perpendicular conformation in which the guanidine moiety lies at a 90° angle to the phenyl ring, perhaps “fixed” by the exocyclic C=N double bond (Avbelj and Hadzi, 1985; Roth and Fenner, 2000). The ability of clonidine to adopt this perpendicular conformation appears to permit a nearly identical sterical conformation as the catecholamine neurotransmitter norepinephrine. Using docking simulations, Salminen and colleagues suggested that both clonidine and norepinephrine were able to form two hydrogen bonds with Asp113 in the binding pocket of α_{2A} (Salminen et al., 1999). In contrast, the naphazoline-type α -sympathomimetics are not constrained by similar substituents and are likely free to rotate and assume a coplanar form. A general prerequisite for the strong antihypertensive effect of clonidine and related drugs has been found to be an impediment of free rotation of the phenyl ring around the C-N single bond (Roth and Fenner, 2000). Given the stereo selective nature of the α_2 -receptor (2.5.1.), this “fixed” conformation of clonidine, compared to

naphazoline, may well determine the selectivity for α_2 - and α_1 -receptors, respectively.

Fig. 10: Tautomeric isomers of clonidine. *The 2-amino imidazoline structure of clonidine facilitates a shift of the imidazoline C=N double bond to the bridging amino nitrogen. Upon protonation of the molecule, the positive charge is more evenly distributed over the molecule (+M effect of the ortho-chlorophenyl substituent and the free electron pairs of the two imidazolidine nitrogen atoms). Consequently, clonidine may be more correctly described as a guanidine derivative than a 2-imidazoline compound.*

While effective as a topical vasoconstricting agent, clonidine proved to possess other pharmacological effects that made it undesirable in the treatment of nasal decongestion. Sedation was a known side effect of imidazoline derivatives; however, the bradycardic and hypotensive properties exhibited by clonidine were unexpected, as described by Hoefke and Kobinger in 1966. These unique qualities led to the realization of a new class of centrally acting antihypertensive drug. While clonidine (Catapresan[®]) remains the classic α_2 -imidazoline agonist, it has gradually lost its therapeutic importance as an antihypertensive with the emergence of the newer α_2 -imidazoline compounds rilmenidine (Laubie et al., 1985) and moxonidine (Armah, 1988). These “second generation” central antihypertensives are comparable to clonidine in their ability to lower blood pressure, yet are recognized as eliciting fewer side effects than their predecessor such as sedation and xerostomia.

There is much controversy surrounding the mechanism of action of these centrally acting α_2 -agonists with imidazoline structure depicted in figure 11 (see Szabo, 2002 for a thorough review of both sides). Two general hypotheses can be distinguished to explain the pharmacological target(s) of the antihypertensive effect of these drugs. Prior to the discovery of imidazoline binding sites, the mode of action of clonidine was attributed solely to the activation of α -adrenergic receptors, primarily sympathoinhibitory α_2 -receptors in the medulla oblongata, with a lesser contribution of peripheral α_2 -

autoreceptors (van Zwieten et al., 1984). This α_2 -hypothesis still receives much support (see Guyenet, 1997 for a critical review).

In 1984, however, the imidazoline hypothesis was introduced by Bousquet and colleagues who observed that clonidine, but not α -methylnorepinephrine, lowered blood pressure when injected directly into the rostral ventrolateral medulla (RVLM). Moreover, the authors observed a similar hypotensive effect with two selective α_1 -agonists with imidazoline structure, cirazoline and ST 587, as with clonidine, leading them to speculate that not α_2 -receptors but rather certain “imidazoline-preferring” binding sites mediate the hypotensive effect of centrally acting α_2 -imidazoline agonists (see Bousquet and Feldman [1999] and Ernsberger and Haxhiu [1997] providing evidence in favor of the imidazoline hypothesis). Numerous radioligand binding studies with [3 H]clonidine or clonidine-related radioligands such as [125 I]p-iodoclonidine in various tissues, classically in bovine brain stem, have identified imidazoline binding sites, although the relative selectivity of α_2 -imidazoline ligands to either binding site may vary greatly depending on the tissue and the donating species (see Szabo, 2002 for a comprehensive summary). Therefore, the imidazoline-preferring binding site has remained difficult to define absolutely. Due to the varying affinity of clonidine to these binding sites, three classes of imidazoline binding sites can now be differentiated. I_1 imidazoline binding sites are located in the RVLM and are therefore believed to participate in blood pressure regulation; I_1 binding sites have been found on platelets and in PC-12 cells as well (Piletz et al., 1991; Lanier et al., 1993). The molecular identity of the I_1 site is still unknown. Piletz and colleagues succeeded in isolating the full-length cDNA clone of a protein recognized by an antibody raised against an affinity-purified imidazoline binding protein (Piletz et al., 2000). It is not yet clear, however, if this isolated protein termed “IRAS-1” represents a functional receptor. I_2 binding sites are better characterized and appear to be allosteric binding sites on monoamine oxidase (Tesson et al., 1995). I_3 binding sites may or may not represent a unique class; however, they appear to facilitate insulin release (Morgan and Chan, 2001).

Fig. 11: Structures of α_2 -imidazoline agonists with varying affinities at α_2 -receptors and I_1 binding sites.

3.6. Mice carrying targeted deletions for one or more α_2 -receptor subtypes

3.6.1. Introduction to gene targeting

Genetic manipulation of mouse DNA has become a common technique to elucidate the function and biochemical pathways of proteins. Although the genetic code of many standard laboratory animals is well established, the species *Mus musculus* (the house mouse) has been used nearly exclusively for (mammalian) genetic studies due to its short reproductive cycle and established techniques of introduction of foreign genetic material into germ cells. Two widespread methods of genetic manipulation, transgenesis and mutagenesis (gene targeting), can be distinguished (Silver, 1995).

Unlike transgenesis, gene targeting modifies the endogenous genetic locus of a specific gene. After subcloning the genetic region of interest into a suitable vector, the targeted gene is modified via site-directed mutagenesis to create either a deletion, insertion or a substitution. The genetic construct is then introduced into embryonic stem (ES) cells via homologous recombination (Stryer, 1995). Properly targeted cells are then injected into blastocysts and implanted into the ovary ducts of pseudopregnant foster mice. The mice born are chimera, carrying both wild-type and mutant cells. In case of germline transmission of targeted cells, these chimera become founders of the mutant line (Silver, 1995).

3.6.2. Generation of β_2 -“knockout” mice

Genetic manipulation of the β_2 -receptor has tremendously increased understanding of the individual receptor subtypes. Because of the high homology between the three subtypes and the related lack of subtype-specific ligands, deletion of each subtype has proven a powerful tool in the elucidation of their physiological roles. The first published targeted deletion of an β_2 -receptor subtype was the β_{2C} -“knockout” mouse by Link and colleagues (1995). These mice showed no obvious abnormalities, and no up-regulation in the mRNA levels of the remaining two β_2 -subtypes, suggesting that the β_{2C} -subtype was more or less dispensable (Link et al., 1995). One year later, the same group succeeded in deleting the β_{2B} -subtype (Link et al., 1996). The targeted deletion of the β_{2A} -subtype was not described until three years later (Altman et al., 1999). Loss of the β_{2A} -subtype divulged resting tachycardia in these mice (Altman et al., 1999), which was not evident in mice expressing 80% less of the β_{2A} -subtype due to a mutation of a single amino acid (β_{2A} D79N-mutant, MacMillan et al., 1996).

4. Project goals

Autoinhibitory α_2 -receptors play a key role in the regulation of sympathetic activity. Functionally and molecularly the α_2 -receptor subtypes are very similar. Because no α_2 -ligands with sufficient subtype selectivity are available, mice deficient in two or all three α_2 -receptor subtypes were generated by crossing existing α_2 -KO lines. The first goal of this project was to characterize these α_2 -deficient mice and observe the consequences – if any – of the complete lack of negative feedback control. The comparison to our α_2 -double KO mice allowed us to evaluate the amount of redundancy of the three α_2 -subtypes.

Having successfully generated a sufficiently large population of α_{2ABC} -KO mice, the next goal was to assess the possible actions of α_2 -agonists possessing an imidazoline structure in these α_{2ABC} -KO mice. Represented by the forerunner clonidine, the class of centrally acting antihypertensive drugs, which includes moxonidine and rilmenidine, is generally believed to act not only by activation of α_2 -receptors but also via purported I_1 imidazoline binding sites in the brain stem. Our mouse model devoid of all functional α_2 -receptor subtypes was expected to give us insight into the mechanism of action of clonidine and clonidine-like drugs. These centrally acting antihypertensive drugs failed to decrease resting blood pressure in the absence of α_2 -receptors; however, a significant reduction in heart rate both in anesthetized and conscious α_{2ABC} -KO mice was determined after clonidine administration.

The final goal of this project was to identify the pharmacological target of this α_2 -receptor-independent effect of clonidine. Intriguingly, it became evident that I_1 receptors did not mediate the bradycardia observed after clonidine treatment of α_{2ABC} -KO mice. My studies identified hyperpolarization activated, cyclic nucleotide-gated cation (HCN) channels as a novel target of an α_2 / imidazoline agonist.

III. Methods

1. Generation of \square_2 -deficient mice

1.1. Housing facilities

All mice used in the following experiments were housed in individually ventilated cages of up to 5 mice per cage in a specified pathogen free facility. The mice were exposed to 12 hour light and dark cycles and were allowed free access to pelleted food and water. All experiments were approved by the Animal Care Committee of the University of Würzburg and the Government of Unterfranken, and were performed in accordance with the guidelines of the National Institutes of Health.

1.2. Generation of \square_{2ABC} -KO mice

\square_{2ABC} -knockout mice were generated by crossing the existing \square_{2AC} -KO and \square_{2B} -KO lines. Once homozygous \square_{2ABC} -KOs were obtained, these mice were mated so that all resulting \square_{2ABC} -KO offspring were of purely homozygous origin. The generation of \square_{2A} -KO, \square_{2B} -KO, and \square_{2C} -KO has been described previously (Altman et al., 1999; Link et al., 1995, 1996).

1.3. Genotyping of \square_{2ABC} -KO mice

1.3.1. Preparation of genomic DNA

Approximately 0.5 cm of tail was biopsied and digested overnight at 55° C, shaking constantly, after addition of 200 μ l lysis buffer and 5 μ l proteinase K (20 mg/ml). The next morning, the samples were briefly vortexed and centrifuged (30 s at 13000 rpm). Next, the samples were heated 8 min at 100° C and then centrifuged again for 3 min at 13000 rpm. 1 μ l of the supernatant was used as described below.

lysis buffer

0.5% sodium lauroylsarcosine

0.1 M NaCl

5% Chelex-100

in H₂O

1.3.2. Polymerase chain reaction (PCR)

To confirm the absence of all three α_2 -receptor subtypes, genomic DNA of α_{2ABC} -KO mice was subjected to analysis by means of the polymerase chain reaction (PCR). By using oligonucleotides (= "primers") flanking the modified region of the gene in question, it was possible to amplify the targeted sequence and view the resulting gene fragment under UV light after electrophoretic separation on agarose gel. In addition to the samples, tail biopsies of mice of confirmed genotype (control DNA) as well as a negative control (water instead of DNA to insure the absence of impurities of the reactants) were concurrently subjected to the PCR.

<u>primers:</u>		<u>T_m</u>	<u>fragment size</u>
α_{2A} -WT	5' – GGT GAC ACT GAC GCT GGT TT 5' – AAG GAG ATG ACA GCC GAG AT	56° C	410 bp
α_{2A} -KO	5' – GGT GAC ACT GAC GCT GGT TT 5' – CGA GAT CCA CTA GTT CTA GC	56° C	260 bp
α_{2B} -WT	5' – CTC TTC TGT ACC TCC TCC AT 5' – CAT AGA TTC GCA GGT AGA CG	55° C	320 bp
α_{2B} -KO	5' – TGG ATG TGG AAT GTG TGC GA 5' – CAT AGA TTC GCA GGT AGA CG	55° C	212 bp
α_{2C} -WT	5' – CAT CTT GTC CTC CTG CAT AG 5' – TCT CAT CCG GCT CCA CTT CA	57° C	230 bp
α_{2C} -KO	5' – GGG AAG ACA ATA GCA GGC AT 5' – TCT CAT CCG GCT CCA CTT CA	57° C	250 bp

PCR:

1 μ l genomic DNA from Chelex digestion
1 μ l forward primer, 10 μ M
1 μ l backwards primer, 10 μ M
2 μ l 10x PCR buffer + MgCl₂
2 μ l dNTPs, 2 mM
0.2 μ l Taq-polymerase 5 U/ μ l
12.8 μ l water for injection
20 μ l total volume for n=1 sample

Over 30 cycles the samples were repeatedly first heated to 94° C (15 s) to denature the double-stranded DNA, then cooled to the appropriate hybridization temperature of the primers (T_m) to assure annealing of the primers to the single-stranded DNA (20 s), then finally heated again to 72° C (25 s) to allow for elongation of the complementary DNA strand.

1.3.3. Gel electrophoresis

After the PCR, approximately 2 μ l loading buffer was added to the entire contents of each reaction tube, and the samples were loaded into the pockets of a 2% agarose gel. After electrophoretic separation at about 145 V, the gel was examined under UV light (265 nm) and photographed. The position of the sample fragments was compared to the control DNA.

2% agarose gel:

2% agarose dissolved by heating in 1x TAE buffer

50x TAE buffer:

400 mM Tris-HCl
50 mM Na(CH₃COO)
10 mM EDTA
pH = 8

loading buffer:

0.25% (M/V) bromphenol blue

50% (V/V) glycerin

50% (V/V) H₂O

2. Basal characterization of α_{2ABC} -deficient mice

α_{2ABC} -KO mice were generated and maintained on a mixed 129/Sv/C57BL6 genetic background. Due to the lethality of α_{2B} -deficient mice on a pure, congenic C57BL6-background, it was not possible to generate congenic α_{2ABC} -deficient mice. In the initial mating scheme (Results, figure 12), the relative contributions of 129Sv and C57BL6 were 1:16. C57BL6 wild-type mice housed under identical conditions served as controls.

2.1. Determination of urine catecholamines

The catecholamines norepinephrine, epinephrine, dopamine and L-DOPA were examined extensively in our α_{2ABC} -KO mice. Urine catecholamines were bound and purified using the aluminum oxide method, which makes use of the ability of aluminum oxide to selectively bind catecholamines at pH 8.6 and to release them after washing with acid (pH = 1-2). Catecholamines were quantified by means of HPLC on a reversed phase RP-18 column. Peaks were detected electrochemically and quantified using Millennium M32 software (Waters).

Mice (n=2-5) were placed in a metabolic cage for 24 hours and the total urine was collected in a small graduated measuring cylinder containing 1 ml 0.4 M HClO₄ and 1 ml mineral oil to prevent loss of urine volume due to evaporation. Mice had free access to food and water in the metabolic cage. After 24 hours, the total volume of urine in the measuring cylinder was recorded and the aqueous phase was pipetted into a 15 ml Falcon. The samples were stored at -20° C until preparation for measurement. Directly before HPLC analysis, samples were thawed and a 100 μ l sample was added to 500 μ l stabilizing mix (27 mM EDTA, 50 mM Na₂SO₃). Then, 100 μ l 3,4-dihydroxy benzylamine hydrobromide (DHBA) internal standard (100 ng/ml) solution, 300 μ l 2 M Tris pH = 8.2-8.3 and 20 mg aluminum oxide were added. The mixture was shaken well to allow binding of the catecholamines to the aluminum oxide. After 5 minutes, the mixture was filtered and the aluminum oxide was washed twice with water. Finally, the purified catecholamines were eluted twice with

100 μ l 0.1 M HClO₄; the eluate was injected directly into the HPLC system by means of an automatic injector (WISP 717, Waters).

2.2. Determination of the degree of cardiac hypertrophy

Following sacrifice of the mouse by cervical dislocation, the heart was removed and all excess tissue and also the atria were excised. The ventricles were weighed on an analytical balance (Kern, type 370-13). The tibia was also removed and, after trimming away excess tissue, measured using a vernier caliper. The quotient of heart weight divided by tibia length is a widely accepted indicator of cardiac hypertrophy.

Another common measure of hypertrophy is the ratio of heart weight to body weight. Here the mouse was weighed on a balance (Mettler, PM480 DeltaRange) before sacrifice. However, in this case the atria were not removed from the heart before weighing (these hearts were later used in radioligand binding experiments where the binding characteristics of the whole heart were investigated).

2.3. Histology

2.3.1. Organ removal and fixation

After sacrifice by cervical dislocation, the organ(s) of interest was quickly removed, blotted dry on a paper towel and immersed in 4% paraformaldehyde solution in a 6-well plate. The plate was sealed tightly and the organs were stored at 4° C until they could be embedded in paraffin (at least 24 hours).

2.3.2. Preparation of paraffin slices

The organs were removed from the paraformaldehyde solution and washed twice with formalin. Next, water was removed from the tissues by immersing them successively in ethanol / water solutions of increasing concentration (2x 80%, 4x absolute ethanol). Since paraffin is not soluble in ethanol, it was necessary to wash twice with xylol before adding the liquid paraffin. The tissue was warmed to approximately 60° C and saturated with paraffin of the same temperature. The previous steps were carried out by an automated tissue processor. Next the paraffin-coated tissue was positioned in a cassette and embedded in molten paraffin. After a thin film had formed on the cooling

form, cold water was poured onto the form and the form removed from the cassette. The tissue blocks were cut with a microtome (Leica RM2165) into 3-4 μ M sections. The sections were placed in a water bath (37° C) and mounted onto Superfrost slides (Menzel). The slides were dried at 42° C and then stored at 4° C.

2.3.3. Staining with hematoxylin and eosin (HE)

Before staining it was necessary to remove the paraffin coating. This was done by washing the slides with xylol and then rehydrating the tissue with decreasing ethanol / water concentrations (3x absolute ethanol, 1x ethanol 70%) and finally washing with double-distilled water four times. The slides were stained in hemalaun for 10 min, washed with tap water for 10 min, then counterstained with eosin (1% eosin Y ws) for approximately 50 s. The slides were washed twice with Milli-Q[®] water (30 s each). After staining, it was necessary to dehydrate the tissue again, so slides were immersed in increasing ethanol/water concentrations (reverse of above procedure), then xylol. Finally, slides were embedded in Eukitt[®].

hemalaun:

0.1% hematoxylin
5% alaun ($\text{AlK}(\text{SO}_4)_2 \times 12\text{H}_2\text{O}$)
0.02% sodium iodate
5% chloral hydrate
0.1% citric acid

2.3.4. Staining with Sirius red

After removal of paraffin and rehydration of sections as described in 2.3.3., slides were stained 45 min with Sirius red solution. After staining, slides were washed twice with Milli-Q[®] water (30 s each) and then dehydrated as described above. Finally, slides were embedded in Eukitt[®].

Sirius red:

0.1% Direct Red 80 in saturated picric acid

2.3.5. Photographing and evaluation of slides

Slides showing a transverse section through the whole heart were photographed using a Contax 167MT camera attached to the microscope (Zeiss Axiovert 135). The photographs were stored digitally and could be evaluated later in Photoshop.

To assess the degree of hypertrophy by comparing the sizes of individual cardiac myocytes (HE-stained), a photograph showing approximately 10 myocytes (under 63x magnification) in cross-section was evaluated. Using the lasso tool, the individual myocytes were carefully outlined one after another and filled in with paint. Under the “picture” column and “histogram”, the pixel size of the myocyte was calculated by Photoshop. The pixel sizes of the myocytes (approximately 10 per slide x 5 slides) were averaged for each group and the group means were compared.

To assess the degree of fibrosis, Sirius red-stained slides were compared. Under low magnification (5x) the major cavity was centered in the field of view and then photographed. Next, the papillary muscle was focused under 20x magnification and photographed. Finally, the tissue areas directly to the right and left of the papillary muscle (viewed such that the major cavity is directly above the papillary muscle) that do not show the cavity wall were photographed under 20x magnification. In Photoshop the pipette tool was selected. The pipette was clicked on fibrotic areas (red in Sirius red stain) to select the color intensity. A tolerance of 40 was entered under the “selection” column and “select colored region”. Then, under the “picture” column and “histogram”, the number of pixels shown was recorded.

3. Radioligand binding

3.1. Preparation of membranes from tissues

After sacrifice of the mouse by cervical dislocation, the organ(s) was quickly removed, freed from excess tissue and frozen immediately in liquid nitrogen. The tissues were stored at -80° C until homogenization. The frozen tissue was homogenized in 2 ml 0.32 M sucrose on ice with a glass Dounce homogenizer. After centrifugation of the homogenate 10 min, 4500 rpm, 4° C in a tabletop centrifuge (Rotina 48 R), the supernatant was poured into an

ultracentrifuge tube, balanced, and centrifuged 40 min at 37000 rpm, 4° C in a Ti70 rotor (Beckman LE-70 ultracentrifuge). The supernatant was discarded and the pellet resuspended in 1 ml Milli-Q[®] water with a disposable 1 ml syringe. After another 30 minutes of centrifugation at 37000 rpm and 4° C, the pellet was resuspended in 1 ml 50 mM Tris, pH = 7.4 and centrifuged a final 30 min at 37000 rpm, 4° C. The pellet was resuspended in approximately 400 μ l 50 mM Tris, pH = 7.4 per homogenized organ. The protein content of the resulting membrane suspension was determined by the Bradford method (see 3.2.).

3.2. Quantification of proteins: Bradford assay

The Bradford dye assay to determine the protein concentration in a solution makes use of the pH-induced changes in equilibrium of Coomassie Blue G dye. Upon binding to a protein, the red doubly-protonated form of Coomassie Blue G goes via an intermediate single-protonated green form into the blue protein-bound unprotonated form (Bradford, 1976). This protein / dye complex is stable and can be quantified photometrically by measuring the absorbance of the sample at 595 nm.

In a disposable plastic cuvette, approximately 1-5 μ l of the membrane solution obtained under 3.1. was added to a 1:5 dilution of the Bradford reagent 5x concentrate (Roti[®]-Nanoquant, Roth) to yield a total volume of 1 ml. After 20 minutes, the absorbance of the sample at 595 nm was measured against the protein-free Bradford dilution using a spectrophotometer (Shimadzu UV-1601). Each membrane suspension was measured in triplicate.

The protein concentration of the measured membrane suspension was calculated using a calibration curve generated with bovine serum albumine as a standard.

The membrane suspension was diluted with Tris 50 mM, pH = 7.4 to a final concentration of 2 μ g/ μ l, aliquoted, and frozen in liquid nitrogen. The aliquots were stored at -80° C until binding was performed.

3.3. Saturation binding in α_{2ABC} -KO membranes

Saturation binding experiments were performed to determine the total number of specific binding sites for [³H]clonidine in α_{2ABC} -KO brain and heart

membrane preparations. The nonspecific binding of the radioligand to other sites (determined in the presence of an excess of non-radioactive clonidine) was subtracted from the total binding in α_{2ABC} -KO membranes to yield the specific binding of [3 H]clonidine.

The specific binding curve obtained by subtraction of the nonspecific binding curve from the total binding curve is characterized by the number of binding sites B_{max} and by the dissociation constant K_d , the concentration of ligand at which 50% of the binding sites are occupied. B_{max} and K_d can be determined using the following equation:

$$Y = \frac{B_{max} * X}{K_d + X}$$

X radioligand concentration [nM]
Y specific binding in cpm or fmol/mg at **X**

The above equation assumes one site binding.

To first assess whether or not α_{2ABC} -KO mouse membranes exhibited specific binding possibly attributable to I_1 -imidazoline receptors (originally proposed by Bousquet et al., 1984), membrane preparations of α_{2ABC} -KO brain and heart (see 3.1.) were subjected to saturation binding experiments with the “classic” mixed α_2 / I_1 agonist [3 H]clonidine. Total binding and nonspecific binding of the radioligand were determined as follows:

total binding:

100 μ l 50 mM Tris buffer, pH = 7.4
 50 μ l 2 μ g/ μ l membrane suspension
 50 μ l [3 H]clonidine (2-64 nM)

nonspecific binding:

50 μ l 50 mM Tris buffer, pH = 7.4
 50 μ l 2 μ g/ μ l membrane suspension
 50 μ l 40 μ M clonidine
 50 μ l [3 H]clonidine (2-64 nM)

[3 H]clonidine:

working conc.

2 nM
 4 nM
 8 nM
 16 nM

end conc.

0.5 nM
 1 nM
 2 nM
 4 nM

24 nM	6 nM
32 nM	8 nM
64 nM	16 nM

The [³H]clonidine stock solution (18 μM) was first diluted 1:100 with 50 mM Tris buffer, pH = 7.4, then the radioligand dilution was diluted again with Tris buffer to yield the necessary amount of each working concentration. Each concentration was determined in triplicate (3x total binding, 3x nonspecific binding). Filter counts (150 μl 50 mM Tris buffer and 50 μl radioligand) were determined in duplicate, and total counts were measured once per concentration. The reagents were pipetted on ice, vortexed briefly, spun down, then incubated at room temperature for 1 hour. After this time, samples were placed on ice, and the reaction was stopped by rapid vacuum filtration over GF/F glass fiber filters which were incubated at least 20 minutes prior to filtration in 0.33% polyethylenimine (PEI) in 50 mM Tris buffer on ice. Each filter was washed 3x with ice-cold 50 mM Tris buffer, then placed in a 5 ml scintillation vial. After all samples were filtered, the vials were filled with 4 ml Lumasafe scintillation solution, closed, and shaken. After at least 2 hours, the samples were counted in a Beckman LS 1801 β -counter. The results were analyzed using Prism GraphPad software to determine B_{max} and K_d values.

3.4. Competition binding in α_{2ABC} -KO membranes

Competition binding studies allow the determination of the affinities of a wide range of compounds at a given receptor in the presence of a single concentration of radioligand with a known K_d at that receptor. Samples are incubated with increasing concentrations of the non-radioactive ligand, and then the amount of radioligand still bound at that concentration is counted. By plotting the logarithmic concentration of the inhibitor against the bound radioligand (cpm), a sigmoidal dose-response curve is obtained, yielding the IC_{50} value of the ligand of unknown affinity. This inflection point is where 50% of the specific binding of the radioligand is displaced by the non-radioactive ligand. With the IC_{50} value, it is possible to calculate the K_d value of the inhibitor [K_i] by means of the Cheng-Prusoff equation:

$$K_i = \frac{IC_{50}}{1 + [L]/K_d}$$

[L] = total concentration of radioligand in sample [nM]
 [K_d] = known K_d of radioligand at the receptor [nM]

To better define the non- α_2 binding site for [^3H]clonidine in $\alpha_{2\text{ABC}}$ -KO membranes, other known mixed α_2 / I_1 agonists with previously defined I_1 affinities were examined under the current experimental conditions. Samples were incubated with increasing concentrations of non-radioactive ligand (1 nM, 10 nM, 100 nM, 0.5 μM , 1 μM , 10 μM) and 8 nM [^3H]clonidine for one hour at room temperature as follows:

competition binding:

50 μl 50 mM Tris buffer, pH = 7.4
50 μl 2 $\mu\text{g}/\mu\text{l}$ membrane suspension
50 μl 4x ligand solution
50 μl [^3H]clonidine (32 nM)

In addition, three blank values (= total binding of radioligand) were included. All samples were analyzed in triplicate. After one hour, samples were placed on ice, and the reaction was stopped by rapid vacuum filtration over GF/F glass fiber filters which were incubated at least 20 minutes prior to filtration in 0.33% PEI in 50 mM Tris buffer on ice. Each filter was washed 3x with ice-cold 50 mM Tris, then placed in a 5 ml scintillation vial. After all samples were filtered, the vials were filled with 4 ml Lumasafe scintillation solution, closed, and shaken. After at least 2 hours, the samples were counted in a Beckman LS 1801 β -counter. The results were analyzed using Prism GraphPad software to determine IC_{50} values for the tested ligands.

All ligands, with the exception of rilmenidine, were dissolved in Milli-Q $^{\text{®}}$ water to 10 mM stock solutions, then diluted with 50 mM Tris buffer, pH = 7.4 to the working concentration. Due to poor water solubility, rilmenidine was first dissolved in 30% ethanol to yield the 10 mM stock solution, then diluted as above with 50 mM Tris buffer, pH = 7.4.

4. Functional characterization of $\alpha_{2\text{ABC}}$ -deficient mice after α_2 -agonist application

4.1. Assessment of analgesic efficacy

A tail-flick test (Ugo Basile model 7360, IR intensity = 40) was used to measure the analgesic efficacy of clonidine, moxonidine and rilmenidine (50

μg per mouse) in wild-type and $\alpha_{2\text{ABC}}$ -KO mice. The mean duration of 10 measurements taken for the mouse to remove its tail before agonist injection was compared to the mean duration of 10 measurements taken 15 minutes after injection. Only 5 post-injection measurements were performed in wild-type clonidine-injected mice to reduce harm to the animal.

4.2. Measurement of sedative properties

A rotarod model was used to assess the sedative effect of clonidine in wild-type and $\alpha_{2\text{ABC}}$ -KO mice. The rod rotated at a speed of approximately 15 rpm. After a brief training period, 5 measurements were taken before and 15 minutes after clonidine, moxonidine, rilmenidine or medetomidine ($50 \mu\text{g}$ / mouse) administration in 6 wild-type and 6 $\alpha_{2\text{ABC}}$ -KO mice.

4.3. Determination of blood glucose

Mice were briefly anesthetized with 4% isoflurane gas in oxygen, administered by a nose mask. Following loss of consciousness, the isoflurane content in the oxygen was reduced to 1.5-2%, depending on the animal's reactivity. 1-2 drops of blood were collected per sample using a 1 cm long glass capillary from the retroorbital venous plexus. The blood sample was immediately applied to the Accu-Chek Sensor Comfort test strip already placed in the Accu-Chek Sensor glucose meter (Roche), and the result was recorded in an Excel sheet.

4.4 Measurement of cardiovascular parameters

4.4.1. Blood pressure

In mice anesthetized with 2% isoflurane, blood pressure was determined by catheterization of either the left ventricle or aorta using a 1.4F high-fidelity pressure-volume catheter (Millar Instruments). The measurements were recorded using PowerLab Chart software for Macintosh (AD Instruments, Australia). Agonists and antagonists were administered, unless otherwise stated, intraperitoneally (ip) in a physiological saline solution. Mice remained on a heated table (37°C) throughout the measurements to avoid temperature-dependent changes.

Telemetric measurement of resting blood pressure in awake, unrestrained \square_{2ABC} -KO and age-matched wild-type mice (n=6 per group) was also performed to eliminate a possible influence of the anesthetic on blood pressure. 10-20 days after implantation of the sensor (PA10; DSI, Transoma Medical, USA), the mean 24-hour blood pressure was recorded in wild-type and \square_{2ABC} -KO mice (n=6 per group).

4.4.2. Heart rate

In isoflurane-anesthetized mice (2% in O₂ via a nose mask), heart rate was monitored after insertion of a 1.4F high-fidelity pressure-volume catheter (Millar Instruments) into the femoral artery. Blood pressure measurement was not possible in the femoral artery. The measurements were recorded using PowerLab Chart software for Macintosh (AD Instruments, Australia) after the mouse was placed on a heated table (37° C). Agonists and antagonists were applied, unless otherwise stated, intraperitoneally (ip) in a physiological saline solution.

Baseline heart rate of both wild-type and \square_{2ABC} -KO mice was determined in conscious, freely-moving mice by means of pressure telemetry (sensor PA10, DSI, Transoma Medical, USA) after implantation of an indwelling catheter in the left carotid artery. The mean 24-hour heart rate of \square_{2ABC} -KO and age-matched wild-type mice (n=6 per group) was recorded 10-20 days after surgical implantation of the telemetric sensor. Agonist-induced changes in beating frequency were also evaluated in awake, unrestrained mice using ECG telemetry (sensor TC10, DSI). Clonidine-induced bradycardia was recorded in \square_{2ABC} -KO and age-matched wild-type mice (n=6 per group) 10-20 days after surgical implantation.

4.4.3. Contractile function

In order to evaluate left ventricular function in \square_{2ABC} -KOs, shortening fraction was measured via echocardiography. After light sedation with tribromoethanol (200 μ l 2.5% solution ip), transthoracic echocardiography Doppler examinations were performed in wild-type and \square_{2ABC} -KO mice (n=6 per group) with an echocardiographic system (Acuson, Sequoia C512, Siemens AG, Erlangen) utilizing a 15-Mhz linear transducer. Measurements were performed offline by a blinded observer in accordance with the recommendations of the American Society of Echocardiography.

4.5. Organ bath

After sacrifice of the mouse by cervical dislocation, the heart was rapidly but carefully removed and placed in a silicon-coated Petri dish filled with a modified Tyrode's solution, pH-adjusted with carbogen gas. The atria were then completely excised from the ventricles, pinned down with a 27-gauge needle and closely observed to identify the right atrium. Using a fine thread (Danville's 6/0 Flymaster waxed), a loop was formed and the sides of the atrium were "lassoed" and knotted. One thread from each knot was removed, and the remaining threads were affixed with tissue adhesive (Histoacryl) to either a thin wire (upper thread) or to the hook (lower thread) of the force transducer. The four chamber organ bath (FMI GmbH, type IOA-5301) was prefilled with the modified Tyrode's solution, tempered to 37° C by an outer heating coil. Each atrium was gently stretched by shortening the wire so that a normal contraction rate of 300-500 bpm resumed. After this, the amplifier was zeroed. The spontaneous contractions of the right atria were registered by PowerLab Chart software for Macintosh (ADInstruments).

Ligands were added in increasing concentrations from 100x stock solutions (to yield end concentrations of 1 nM – 1 mM in tenfold steps) to the 3 ml bath solution. Once the effective concentration range of the ligand was determined, only one or two concentrations were administered to the bath. Both dilution error as well as the accumulation of the ligand was neglected in the evaluation.

modified Tyrode's solution

119.77 mM NaCl
5.36 mM KCl
2.13 mM MgCl₂
22.6 mM NaHCO₃
0.48 mM NaH₂PO₄
1.2 mM CaCl₂
10 mM glucose
2 mM sodium pyruvate
0.28 mM ascorbic acid
pH adjusted to 7.4 with carbogen

4.6. Neurotransmitter release experiments

The release of [³H]norepinephrine from adrenergic neurons was measured in the absence and in the presence of the agonists norepinephrine and medetomidine in isolated cardiac atria from wild-type and α_{2ABC} -KO mice. Briefly, the hearts of mice killed by cervical dislocation were quickly removed and placed in Krebs-Henseleit buffer (see below), taking care not to injure the atria. In a buffer-filled Petri dish the atria were precisely separated from the ventricles and other remaining tissues with the aid of a magnifying glass. Using a small pair of dissection scissors, the atria were opened by cutting from the mitral or tricuspid valve opening along the septum until the atrium resembled a butterfly. Next, the atria were incubated in ca. 0.1 μ M [³H]norepinephrine for one hour, rinsed, then placed in isolated chambers bounded above and below by electrodes. Following [³H]norepinephrine uptake, 1 μ M desipramine was added to the buffer for the remainder of the experiment. After 60 minutes equilibration time in the buffer-perfused chamber, the atria were electrically stimulated according to a fixed protocol (see below) and the perfusate was collected over 8 minutes at 2 minute intervals. The stimulation protocol below describes only one measurement “set”, i.e. for agonist-free (baseline) or for one concentration of agonist. In a typical experiment, 6 such sets were repeated in succession to establish a dose-response curve. Medetomidine and norepinephrine were added (separately) to the buffer reservoir in increasing concentrations after an initial baseline measurement.

Krebs-Henseleit buffer (atria)

118 mM NaCl
 4.8 mM KCl
 2.5 mM CaCl₂
 1.2 mM MgSO₄ x 7H₂O
 25 mM NaHCO₃
 1.2 mM KH₂PO₄
 0.03 mM Na₂EDTA
 11 mM glucose
 0.57 mM ascorbic acid
 pH adjusted to 7.4 with carbogen

stimulation protocol

t = 0-2 min: basal collection interval
 t = 2 min: stimulation interval

- 20 V
- 20 pulses
- 2 ms
- 50 Hz

t = 2-4 min: collection interval
 t = 4-6 min: collection interval
 t = 8-20 min: rinse; no collection

5. Cell culture

5.1. HEK293 cells stably expressing HCN channel subtypes

5.1.1. Culture

Stably transfected HEK293 cells expressing the murine HCN1, the murine HCN2 and the human HCN4 subtypes were generated in the lab of Prof. Dr. Martin Biel at the Ludwig-Maximilians-Universität in Munich. HCN-HEK293 cells were maintained in DMEM high glucose containing 10% fetal calf serum, 100 U/ml penicillin, 100 μ g/ml streptomycin and G418 (at an end concentration of 0.2 mg/ml) to maintain selection pressure. The cells were incubated at 37° C and 10% CO₂.

5.1.2. Electrophysiological measurements in HCN-HEK293 cells

The I_f current in transfected HEK293 cells was measured in Munich using the whole cell patch clamp technique at room temperature. Measurements were conducted at varying extracellular ion concentrations as well as at different voltages. Data were recorded at 10 kHz with the aid of an Axopatch 200B amplifier and pClamp 8 (Axon Instruments). The current amplitude and half-maximum activation voltage V_{0.5} were calculated with the acquired data. In addition, a dose response curve was created to reflect the dose-dependent inhibition of HCN channels (and therefore the I_f current) by clonidine.

5.2. Sinoatrial node (SAN) cells

Located in the sinus node, these cells are characterized by their unstable resting potential which leads to the generation of each new heart beat. HCN channels (as well as others which regulate heart rate, see Introduction 1.2.2.) are located at the cell membrane of SAN cells, making these cells an ideal system in which to study the physiological response to HCN blockade.

5.2.1. Isolation

SAN cells were isolated based on the protocol developed by Mangoni and Nargeot (2001) from age-matched adult wild-type and \square_{2ABC} -KO mice in the lab of Prof. Dr. Martin Biel. Briefly, the beating heart was removed from the anesthetized mouse and immediately placed in pre-warmed Tyrode's solution,

where the sinoatrial region was removed and cut into tissue strips. These strips were then placed in a Ca^{2+} - and Mg^{2+} -deficient solution. The SAN tissue strips were digested by collagenase type II, elastase, protease, BSA 1 mg/ml and $200 \mu\text{M}$ CaCl_2 , all added to the low Ca^{2+} and Mg^{2+} solution. The tissue strips were intermittently dissociated with a glass Pasteur pipette during 9-13 minutes of digestion at 35°C . Afterwards, SAN strips were washed and placed in a modified high K^+ medium. Further agitation of the tissue strips made an isolation of single SAN cells possible, which were returned to a more physiological solution. After readaptation to the physiological extracellular Ca^{2+} concentration, SAN cells were placed in storage medium.

<u>Tyrode's solution</u>	<u>low Ca^{2+} / low Mg^{2+}</u>	<u>digestion solution</u>
140 mM NaCl	140 mM NaCl	229 U/ml collagenase
5.4 mM KCl	5.4 mM KCl	type II

20 mM KCl	35 mM KCl	
80 mM KOH	1.3 mM CaCl_2	
10 mM D- β -OH-butyric acid	0.7 mM MgCl_2	
10 mM KH_2PO_4	14 mM L-glutamic acid	
10 mM taurine	2 mM D- β -OH-butyric acid	
1 mg/ml BSA	2 mM KH_2PO_4	
10 mM Hepes-KOH	2 mM taurine	
pH = 7.4	1 mg/ml BSA	
	50 $\mu\text{g/ml}$ gentamycin	
	pH = 7.4	

5.2.2. Electrophysiological measurements in SAN cells

I_f currents in SAN cells were measured using the whole cell voltage clamp technique at room temperature. Measurements were conducted at varying extracellular ion concentrations as well as at different voltages. Data were recorded at 10 kHz with the aid of an Axopatch 200B amplifier and pClamp 8 (Axon Instruments). The current amplitude and half-maximum activation voltage $V_{0.5}$ were calculated with the acquired data. In addition, a dose response curve was created to reflect the dose-dependent inhibition of HCN channels (and therefore the I_f current) by clonidine.

IV. Materials

1. Oligonucleotides

Oligonucleotide primers were obtained from MWG Biotech GmbH, Ebersberg.

2. Enzymes

collagenase type II	Worthington
elastase	Roche
protease	Sigma

3. Ligands and chemicals

agmatine	Sigma
AGN 192403	Tocris
atipamezole	Antisedan [®] , Pfizer
carbachol	Sigma
cimetidine	Sigma
clonidine	Sigma
efaroxan	Tocris
[³ H]clonidine	New England Nuclear
[³ H]norepinephrine	Amersham
[³ H]RX 821002	Amersham
isoflurane (Forene [®])	Abbott
isoproterenol	Sigma
Lumasafe plus	Lumac
medetomidine (Domitor [®])	Pfizer
moxonidine	Sigma
pertussis toxin	Sigma
rilmnidine	Tocris
ZD 7288	Tocris

Unless otherwise stated, all chemicals were purchased from Sigma Aldrich, Germany.

4. Solutions

Buffer solutions were prepared with Milli-Q[®] water according to protocol. Agonists / antagonists were dissolved in water for injections to yield a 10 mM stock solution. These stock solutions were then diluted with the appropriate buffer (i.e. 50 mM Tris, pH =7.4 for binding and modified Tyrode's solution for organ bath experiments) or with sterile 0.9% NaCl water for injections for in vivo application. Rilmenidine was an exception; due to its poor water solubility, it was first dissolved in 30 parts ethanol 96%, then filled up with 70 parts Milli-Q[®] water to yield a 10 mM stock solution. The rilmenidine stock solution was then diluted as with the other ligands.

5. Cell culture / tissue culture media

DMEM high glucose	Invitrogen
FCS	Biochrom
Penicillin/Streptomycin	Biochrom
Trypsin EDTA	Invitrogen
G418 (geneticin)	Roche

6. Other materials

Accu-Chek Sensor glucose meter	Roche
Accu-Chek Sensor Comfort test strip	Roche
Carbogen (95% O ₂ , 5% CO ₂)	Linde, Unterschleißheim
Glass slides	SuperFrost Menzel
GF/F glass fiber filters	Millipore

Plastic tubing, syringes, needles, forceps, scissors, glass capillaries and other miscellaneous equipment were obtained from the company Hartenstein in Würzburg.

V. Results

1. Characterization of α_{2ABC} -KO mice

1.1. Genotyping of α_{2ABC} -KO mice

Mice carrying a targeted deletion in one, two, or all three α_2 -receptor subtypes were generated as described previously (Philipp et al., 2002c). Figure 12 shows a simplified scheme for the generation of α_{2ABC} -KO mice by crossing the two preexisting knock-out lines α_{2AC} -KO and α_{2B} -KO. This project began with approximately 10 adult α_{2ABC} -KO mice, despite the low survival rate of α_{2ABC} -KO embryos. Interbreeding of mice deficient in α_{2A} - and α_{2C} -subtypes but heterozygous for α_{2B} ($\alpha_{2A-/-B+/-C-/-}$) suggested that less than one of every 250 ($\alpha_{2A-/-B-/-C-/-}$) embryos was born and survived until weaning at three weeks of age (Philipp, 2002b). Nevertheless, these mice were paired, and a few litters were produced. This younger generation of α_{2ABC} -KOs produced more offspring than the original breeding pairs. With each generation, litter size and frequency appeared to increase, until six months later over 100 α_{2ABC} -KO mice were recorded.

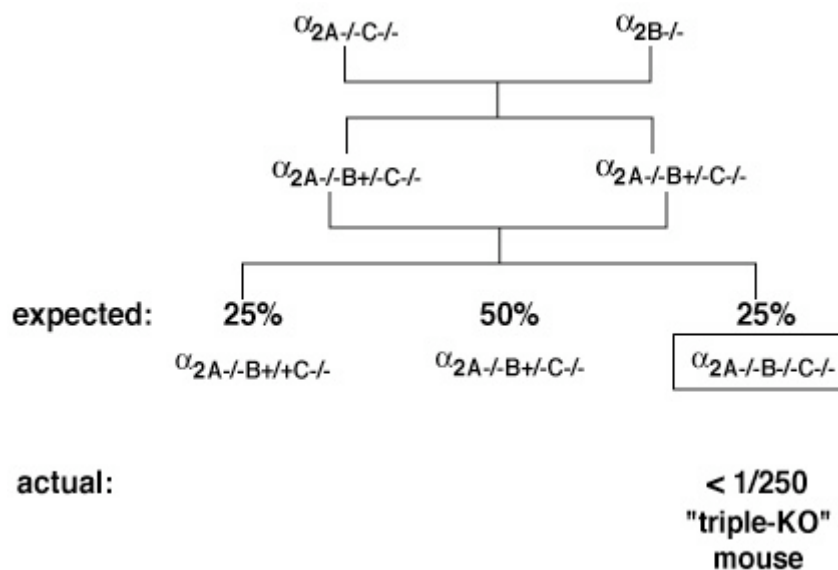

Fig. 12: Generation scheme for mice deficient in all three α_2 -receptor subtypes. α_{2B} -KOs were mated with α_{2AC} -double KOs; their offspring were

interbred to yield mice lacking α_{2A} - and α_{2C} -subtypes but heterozygous for α_{2B} ($\alpha_{2A^{-}/B^{+}/C^{-/-}$). These mice were paired. Mendelian genetics predict 25% of their offspring to be α_{2ABC} -KOs; however, a much lower percentage of α_{2ABC} -KOs were born than expected.

The α_{2ABC} -KO mice studied in the course of this project resulted solely from the homozygous matings of the approximately 10 “original” α_{2ABC} -KOs generated by the above scheme. Their genotype had been confirmed by PCR (see Methods, chapter 1.3.) using primers that annealed to the α_2 -DNA contained in the targeted allele on either end of the deleted base pairs as depicted in figure 13a. Four PCR reactions were performed to verify the genotype of α_{2ABC} -KOs. While the wild-type and targeted alleles for α_{2A} and α_{2B} could be identified in a single PCR reaction, separate PCR reactions were necessary to distinguish the α_{2C} alleles. Figure 13b depicts a representative PCR analysis for wild-type mice and mice heterozygous and homozygous for the deletion of the given α_2 -subtype.

Fig. 13: Generation of mice deficient in α_{2A}^{-} , α_{2B}^{-} and α_{2C} -receptor subtypes. *a*, A simplified representation of the targeted alleles in α_2 -deficient mice. The DNA coding for each α_2 -subtype was disrupted by the insertion of a neomycin resistance cassette, rendering that α_2 -subtype nonfunctional. *b*, Representative genotyping analysis showing ethidium bromide-stained gels with PCR products for wild-type or α_2 -KO alleles. *Adra2a*, *Adra2b* and *Adra2c* are the genes encoding the α_2 -adrenergic receptor subtypes α_{2A} , α_{2B} and α_{2C} ,

respectively. *AWTF*, *BWTF* and *CWTF*: forward primers and *AWTR*, *BWTR* and *CWTR*: reverse primers flanking the modified region of *Adra2a*, *Adra2b* and *Adra2c*, respectively. *NEO* = neomycin resistance gene.

1.2. Radioligand binding

To further characterize the α_{2ABC} -KO mouse, radioligand binding in α_{2ABC} -KO heart and brain membranes was performed. The α_2 -specific antagonist [3 H]RX 821002 confirmed the absence of α_2 -receptor subtypes in α_{2ABC} -KO mice. In addition, [3 H]clonidine binding was extensively studied in α_{2ABC} -KO membranes. Although α_2 -receptor binding was absent, [3 H]clonidine did display high affinity for an unidentified binding site(s).

1.2.1. [3 H]RX 821002 autoradiography and membrane binding

Autoradiography of transverse brain sections from wild-type and α_{2ABC} -KO mice was performed with 4 nM [3 H]RX 821002 (figures 14a-c). No specific binding with the α_2 -specific antagonist [3 H]RX 821002 was detectable in either brain slices or in whole brain membrane preparations of α_{2ABC} -KO mice (Fig. 14b, d). The cortex and hippocampus, areas with a high density of α_2 -receptors, were prominently labeled in wild-type mice (Fig. 14a). No such labeling was seen in α_{2ABC} -KO brain slices (Fig. 14b). In the presence of the specific α_2 -antagonist atipamezole, the binding observed in the wild-type brain slice closely resembled that in the α_{2ABC} -KO brain slice (Fig. 14c). Radioligand binding with wild-type and α_{2ABC} -KO whole brain membrane preparations was also performed (Fig. 14d). 4 nM [3 H]RX 821002 labeled approximately 170 fmol α_2 -receptors per mg protein in wild-type brain membranes. The very low binding in α_{2ABC} -KO membranes was due to non- α_2 binding sites, confirmed by the identical level of binding in wild-type membranes in the presence of 1 μ M atipamezole. At this high concentration of specific α_2 -receptor antagonist, virtually all α_2 -binding sites in wild-type brain membranes were saturated. Both autoradiography as well as competition binding confirmed the lack of functional α_2 -subtypes in α_{2ABC} -KO mice previously verified by PCR genotyping.

Fig. 14: [³H]RX 821002 binding in wild-type (WT) and α_{2ABC} -KO brains. *a-c*, Autoradiography of brain slices. *a*, [³H]RX 821002 binding in untreated wild-type brain slices clearly revealed sites containing a high density of α_2 -receptors. *b*, In contrast, the complete lack of [³H]RX 821002 binding in α_{2ABC} -KO brain slices confirmed the absence of α_2 -receptors. *c*, The α_{2ABC} -KO autoradiograph was indistinguishable from that of the wild-type brain slice incubated with atipamezole. *d*, Radioligand binding in whole brain membrane preparations of wild-type and α_{2ABC} -KO mice. Bars represent the group means \pm SEM of $n=3$ experiments. In contrast to wild-type brain membranes, no specific binding could be detected either in atipamezole-treated wild-type or in α_{2ABC} -KO brain membranes with [³H]RX 821002 ($p < 0.001$).

1.2.2. Saturation binding in wild-type and α_{2ABC} -KO membranes

In order to test whether imidazoline ligands can detect specific binding sites in α_{2ABC} -KO membranes, radioligand binding experiments with [³H]clonidine were performed. [³H]clonidine binding in wild-type brain membranes (figure 15a) demonstrated the high affinity of clonidine for and the density of α_2 -receptors in this organ. In contrast, most of the [³H]clonidine binding was missing in α_{2ABC} -KO brain and heart membranes (Fig. 15b-c). However, α_{2ABC} -KO specific binding curves (Fig. 15b) revealed a small but high affinity binding site in α_{2ABC} -KO brain membranes for [³H]clonidine. A binding site with similar affinity but lower density was identified in α_{2ABC} -KO heart membranes (Fig. 15c).

Clonidine affinity to the I₁-imidazoline binding site has been reported to be in a similar range, though values vary greatly depending on the species and tissue examined (Szabo, 2002). This initial observation led us to conduct further binding experiments in α_{2ABC} -KO tissue. Since the detection of the presence of a small, high affinity binding site was in and of itself not adequate proof of having identified an imidazoline binding site in the absence of α_2 -receptors, competition studies were conducted with ligands possessing mixed α_2 / imidazoline affinity in order to characterize this binding site.

Fig. 15: [³H]clonidine saturation binding curves in wild-type and α_{2ABC} -KO membranes. a, Binding sites for [³H]clonidine in wild-type brain membranes were to a great extent attributable to α_2 -adrenergic receptors. **b**, α_{2ABC} -KO brain membranes displayed approximately one-third of the binding sites of wild-type membranes. **c**, The binding sites in α_{2ABC} -KO heart membranes, though lower in density, showed a comparable affinity to [³H]clonidine as in α_{2ABC} -KO brain membranes. Each data point expresses the triplicate mean \pm SEM of a given sample. The saturation curves depicted above are representative of the binding assays performed in wild-type and α_{2ABC} -KO brain membranes (n=3) and α_{2ABC} -KO heart membranes (n=3), from which the K_d and B_{max} values in the following table (1) were calculated.

	tissue	K_d	B_{max}
WT	brain	1.7 ± 0.2 nM	327 ± 11 fmol/mg
α_{2ABC} -KO	brain	15.0 ± 1.6 nM	113 ± 7 fmol/mg
α_{2ABC} -KO	heart	7.8 ± 2.4 nM	20 ± 3 fmol/mg

Tab. 1: Summary of K_d and B_{max} values for wild-type brain and α_{2ABC} -KO brain and heart membranes with [3 H]clonidine. Approximately two-thirds of [3 H]clonidine-binding sites in mouse brain could be attributed to α_2 -receptors, as whole brain membrane preparations from mice deficient in all three α_2 -receptor subtypes displayed only one-third of the binding site density of those from wild-type mice. Despite the large discrepancy between wild-type and α_{2ABC} -KO B_{max} values, [3 H]clonidine appeared to possess a similar affinity to one or more common binding sites in both wild-type and α_{2ABC} -KO membranes, as K_d values were all in the low nanomolar range.

1.2.3. Competition binding in α_{2ABC} -KO membranes

Since the nature of the high affinity binding site for [3 H]clonidine in α_{2ABC} -KO whole brain and whole heart membranes was not known, competition binding experiments with (non-radioactive) clonidine, moxonidine and rilmenidine were first conducted in order to establish whether or not the binding profile of this site matched that of an imidazoline binding site. While three different imidazoline binding sites have been described (see Introduction 3.5.2.), it was most logical that the I_1 binding site, widely distributed and often in close proximity to α_2 -adrenergic receptors (Dontenwill et al., 1999), would be the best candidate for the “non- α_2 ” binding site found in α_{2ABC} -KOs with [3 H]clonidine.

Fig. 16: [^3H]clonidine competition binding in $\alpha_{2\text{ABC}}$ -KO brain membrane preparations. Below $1\ \mu\text{M}$ concentration, moxonidine did not displace $8\ \text{nM}$ [^3H]clonidine from its binding site on $\alpha_{2\text{ABC}}$ -KO brain membranes, while rilmenidine ($\text{IC}_{50} = 0.25\ \mu\text{M}$) and clonidine ($\text{IC}_{50} = 0.26\ \mu\text{M}$) possessed similar affinities to this binding site. Each data point expresses the mean \pm SEM of $n=3$ experiments (moxonidine and rilmenidine) or $n=5$ experiments (clonidine) performed in triplicate. The IC_{50} values of clonidine ($0.26\ \mu\text{M}$, 95% confidence interval [CI] $0.17\ \mu\text{M}$ to $0.40\ \mu\text{M}$) and rilmenidine $0.25\ \mu\text{M}$, 95% CI $0.11\ \mu\text{M}$ to $0.56\ \mu\text{M}$) were calculated from these competition curves.

Moxonidine and rilmenidine are widely accepted to possess higher I_1 selectivity as compared to clonidine (Ernsberger et al., 1993), which is believed to account for the occurrence of fewer side effects with these “second-generation” central antihypertensives than with the prototype clonidine. Unexpectedly, these two substances showed very different competition binding profiles than clonidine itself (figure 16). Rilmenidine was, however, able to displace just as much of the radiolabeled clonidine as the non-labeled clonidine, suggesting that rilmenidine competed for this non- α_2 binding site in $\alpha_{2\text{ABC}}$ -KO brain membranes as well as clonidine.

A number of imidazoline-containing substances, including the highly selective I_1 -ligand AGN 192403 and the endogenous clonidine displacing substance agmatine (Meeley et al., 1986), were screened at a single concentration of $1\ \mu\text{M}$ to assess their ability to compete with [^3H]clonidine (figure 17). While agmatine, atropine, cimetidine, prazosin, rauwolscine and RX 821002 at $1\ \mu\text{M}$ concentrations did not appear to displace any [^3H]clonidine from its binding site, both AGN 192403 and the “selective” α_2 -antagonist atipamezole were able to do so by approximately 18% and 24% (figure 17), respectively.

Moxonidine and efaroxan, a mixed α_2 / imidazoline antagonist with apparently similar I_1 -binding site affinities (Separovic et al., 1996), were comparable in their ability to displace less than 10% of total [3 H]clonidine binding; these results were not significant.

Fig. 17: Displacement of [3 H]clonidine by α_2 / imidazoline ligands. Assessment of the ability of ligands with reported imidazoline binding site affinity to displace 8 nM [3 H]clonidine from α_{2ABC} -KO brain membranes. Besides clonidine itself, only the high affinity I_1 -ligand AGN 192403 and atipamezole were able to significantly compete with the radioligand for this site ($p < 0.001$, one-way ANOVA).

Although the results from binding experiments indicated that there was a non- α_2 high affinity binding site present in α_{2ABC} -KO brain and heart tissue, it was not possible to identify this site by means of competition binding. While the appreciable ability of AGN 192403, a ligand found to be highly selective for I_1 binding sites (Munk et al., 1996), to compete with [3 H]clonidine for this binding site was indicative of an imidazoline I_1 site, the complete lack of affinity of the endogenous clonidine displacing substance agmatine for this site was not consistent with an I_1 binding profile. The low affinity of moxonidine for this non- α_2 site also did not support the plausibility of an imidazoline binding site. All in all, radioligand binding experiments with [3 H]clonidine did not confirm the existence of previously proposed I_1 , I_2 or I_3 imidazoline binding sites in α_{2ABC} -KO membranes.

1.3. Inhibition of [³H]norepinephrine release

Presynaptic α_2 -autoreceptors control norepinephrine release via a negative feedback mechanism (Starke, 2001). When this safeguard is absent, as in the case of α_{2ABC} -KO mice, catecholamine levels may exceed normal values (see 1.4.). As a functional control of the absence of α_2 -receptors, atria from wild-type and α_{2ABC} -KO mice were preloaded with [³H]norepinephrine and then electrically stimulated to evoke release of the tritiated neurotransmitter. The radioactivity released from the atria was measured before and after addition of exogenous norepinephrine in increasing concentrations from 0.1 nM up to 1 μ M. The agonist norepinephrine stimulated presynaptic α_2 -receptors in wild-type mice, decreasing the amount of [³H]norepinephrine released in a concentration-dependent manner. As expected, the amount of radioactivity released following stimulation of α_{2ABC} -KO atria remained constant over time (figure 18).

Fig. 18: Inhibition of [³H]norepinephrine release in wild-type and α_{2ABC} -KO atria. Electrical stimulation evoked release of the tritiated neurotransmitter in both groups. Norepinephrine applied to the superfusion medium decreased the electrically induced [³H]norepinephrine release in wild-type atria but not in α_{2ABC} -KO atria (n=6 atria per genotype).

1.4. Urine catecholamine levels

The endogenous catecholamine norepinephrine serves as the postganglionic neurotransmitter in sympathetic fibers. Methylation of norepinephrine primarily in the adrenal medulla by the enzyme phenylethanolamine N-methyl

transferase (PNMT) yields the hormone epinephrine. Levels of these catecholamines and their precursors in urine and blood are often elevated in the early stages of heart failure (where symptoms first become manifest), as well as in the presence of some neuroendocrine tumors (e.g. pheochromocytoma). Determination of catecholamine concentration in urine collected over 24 hours was achieved by HPLC followed by electrochemical detection.

Fig. 19: 24-hour urine norepinephrine in wild-type and α_2ABC -KO mice. HPLC measurement of 24-hour urine collected from wild-type ($n=10$) and α_2ABC -KO ($n=8$) mice revealed significantly elevated norepinephrine levels in mice deficient in all three α_2 -subtypes (* $p < 0.05$).

1.5. Adverse cardiovascular consequences of the deletion of all three α_2 -receptor subtypes

Because of the critical role played by α_2 -receptors as autoinhibitors of norepinephrine release in both central and peripheral sympathetic nervous system compartments, it was anticipated that deletion of all three α_2 -receptor subtypes would have some, if not detrimental, effects on the cardiovascular system. In order to assess any morphological or functional abnormalities in blood vessels and heart, blood pressure, heart rate and left ventricular function were determined and hearts were examined both macroscopically as well as microscopically.

1.5.1. Resting blood pressure and heart rate

A microtip catheter inserted into the left ventricle was used to measure resting blood pressure and cardiac function in isoflurane-anesthetized mice. Compared to wild-type mice, α_{2ABC} -KO mice showed a significantly higher resting blood pressure (figure 20). Of the three α_2 -double KO lines, only the α_{2AC} -KO mice displayed hypertension in their resting blood pressure. The other two double-KO lines did not differ significantly from wild-type mice (not shown). These findings corroborate previous data demonstrating the relative contribution of each α_2 -subtype to presynaptic inhibition of norepinephrine release (Hein et al., 1999; Trendelenburg et al., 2003).

Fig. 20: Resting diastolic blood pressure in wild-type and α_{2ABC} -KO mice. Mice lacking all three α_2 -receptor subtypes displayed significantly higher resting blood pressure than wild-type mice ($p < 0.001$, one-way ANOVA, $n=6-8$).

In order to confirm that the elevated blood pressure in α_{2ABC} -KO mice was not related to the anesthetic, these measurements were later repeated with awake, unrestrained α_{2ABC} -KO and age-matched wild-type mice. Resting blood pressure in these mice was determined by pressure telemetry with an indwelling catheter placed in the left carotid artery (figure 21). Although baseline blood pressure was markedly higher in both groups, means of both diastolic and systolic blood pressure recorded over a 24-hour period of α_{2ABC} -KO mice were nearly 30 mm Hg higher than the wild-type means. This difference in blood pressure between the groups was similar to that observed in anesthetized mice, suggesting that isoflurane affected both groups equally.

Fig. 21: 24-hour mean resting systolic (a) and diastolic (b) blood pressure in awake, freely-moving wild-type and α_{2ABC} -KO mice. With the aid of pressure telemetry, the significantly higher basal blood pressure in α_{2ABC} -KOs compared to age-matched wild-type mice could be determined without possible obscuration by anesthesia. Blood pressure measured in the aorta of α_{2ABC} -KO mice was higher both during systole and diastole than in wild-type mice (* $p < 0.05$, unpaired t test, $n=6$ per group).

Resting heart rate was likewise determined by means of pressure telemetry as described above. The lack of feedback inhibition by α_2 -adrenergic receptors not only significantly increased blood pressure but also basal heart rate in α_{2ABC} -KO mice compared to age-matched wild-type controls (figure 22). The mean beating frequency over a 24-hour period measured in α_{2ABC} -KO mice was over 50 beats per minute higher than in wild-type controls.

Fig. 22: 24-hour mean heart rate in awake, unrestrained wild-type and α_{2ABC} -KO mice measured with pressure telemetry. On average, α_{2ABC} -KO mice displayed a significantly higher beating frequency (approximately 585 bpm) compared with wild-type controls (520 bpm). Each bar represents the group mean of $n=6$ mice \pm SEM (* $p < 0.05$, unpaired t test).

1.5.2. Cardiac hypertrophy

Two common methods to assess the degree of cardiac hypertrophy are the comparison of the heart weight [mg] to tibia length [mm] ratios (figure 23a) as well as the comparison of heart weight [mg] to body weight [g] (figure 23b). The latter ratio in a “normal” healthy mouse without obesity or cardiac hypertrophy or remodeling is approximately 5 or less. Values significantly higher (≥ 6) than age-matched healthy controls are indicative of the presence of cardiac hypertrophy.

Fig. 23: Cardiac hypertrophy in α_{2ABC} -KO mice. *a*, Ratio of heart weight [mg] to tibia length [mm] in wild-type and α_{2ABC} -KO mice. Each bar represents the group mean \pm SEM. Mice deficient in all three α_2 -receptor subtypes ($n=10$) showed significantly greater ($p = 0.0013$, unpaired t test) ratios than age-similar wild-type mice ($n=5$). *b*, Comparison of the ratio of heart weight [mg] to body weight [g] of 2-4 month old wild-type and α_{2ABC} -KO male mice. Each bar depicts the mean ratio \pm SEM of the respective group. This ratio was again significantly higher ($p = 0.0028$) in α_{2ABC} -KO mice ($n=25$) compared to age-matched wild-type mice ($n=11$).

When examined under a microscope, wild-type and α_{2ABC} -KO hearts showed a significant difference in left ventricular myocyte size. Deletion of all three α_2 -receptor subtypes coincided with increased cross-sectional areas of left ventricular myocytes (figures 24b and 24d). Increased fibrotic tissue was observed in α_{2ABC} -KO myocytes as compared to wild-type myocytes after staining with Sirius red (figure 26). The enlarged myocytes, accompanied by

fibrotic change, substantiated the role of autoinhibitory α_2 -receptors when compared with wild-type myocytes.

Fig. 24: *Cross-sectional view of left ventricle from wild-type and α_{2ABC} -KO mice with HE-staining. a-b, View of left ventricular cavity at low magnification from a representative wild-type (a) and α_{2ABC} -KO (b) mouse. c-d, View of left ventricular wall adjacent to the papillary muscle at a higher magnification from a representative wild-type (c) and α_{2ABC} -KO (d) mouse. Individual myocytes of WT (n=4) and α_{2ABC} -KO (n=4) mice were outlined as shown, and the area of each myocyte was determined morphometrically. A total of 10 regions were selected in 3-4 slides per mouse; between 7 and 10 myocytes were quantified per region (results see figure 25).*

Fig. 25: *Mean cross-sectional areas of wild-type and α_{2ABC} -KO left ventricular myocytes. Left ventricular myocytes from WT (n=4) and α_{2ABC} -KO (n=4) mice were obtained as described above (figure 24). Bars depict the group mean \pm*

SEM. In the absence of α_2 -receptors, myocyte area was significantly increased in comparison to wild-type myocyte area ($p=0.0023$; two-tailed unpaired t test).

1.5.3. Fibrosis

Cardiac fibrosis is characterized by an abnormal expansion of the extracellular collagen-rich matrix surrounding cardiac myocytes. Matrix fibers may grow in the presence of an acute stimulus (i.e. myocardial infarct) or after long-term exposure to hypertension or coronary atherosclerosis, resulting in remodeling of cardiac tissue and an impairment of myocyte contractile function. A reduced contractility that results in a sufficiently great impairment of left ventricular function may ultimately precipitate overt heart failure.

Cross-sectional slices of ventricles from male wild-type and α_{2ABC} -KO mice (6-9 months) showed widespread interstitial fibrotic changes in the α_{2ABC} -KO left ventricle. In contrast, the wild-type ventricle showed virtually no fibrosis (figure 26). This is not surprising given the significantly higher resting blood pressure observed in α_{2ABC} -KO mice in comparison to wild-type mice (see figure 20).

Fig. 26: Cross-sectional view of wild-type (a) and α_{2ABC} -KO (b) hearts. Sirius red staining of cross-sectional slices under 5x magnification revealed extensive cardiac fibrosis in the left ventricle of male α_{2ABC} -KO mice (b) but not in wild-type mice (a) at 6-9 months of age.

1.5.4. Left ventricular function

One widely used parameter to assess cardiac function is shortening fraction, which measures the percent decrease in left ventricular (LV) diameter during contraction in relation to the left ventricular diameter at the end of diastole.

Both left ventricular systolic and diastolic diameters can be obtained by ultrasonic measurement (echocardiography).

To determine what effect – if any – deletion of all three α_2 -subtypes had on left ventricular function, echocardiography was performed on wild-type and α_{2ABC} -KO mice. The LV end diastolic and end systolic diameters were obtained and the shortening fraction was calculated. In wild-type mice, fractional shortening was 50%, while in α_{2ABC} -KO mice this parameter was significantly reduced to 33% (figure 27).

Fig. 27: Fractional shortening in wild-type and α_{2ABC} -KO mice. Bars depict the group mean \pm SEM of the left ventricular function measured in WT ($n=6$) and α_{2ABC} -KO ($n=6$) mice. Mice lacking all three α_2 -receptor subtypes showed a significantly lower shortening fraction than wild-type mice ($p < 0.05$, two-tailed unpaired t test), suggesting that left ventricular function was impaired in the absence of α_2 -receptors.

2. Effects of α_2 / imidazoline agonists in α_{2ABC} -KO mice

2.1. Sedation

One common side effect of clonidine is drowsiness. The sedative qualities of clonidine are believed to be related to its α_2 -receptor affinity; the observation that moxonidine and rilmenidine may cause less drowsiness than clonidine is generally rationalized by the higher I_1 -imidazoline selectivity of these drugs compared to clonidine (for review, see Szabo, 2002). Another possible explanation is that these “second-generation” central antihypertensives are simply less potent than clonidine (Macphee et al., 1992).

A rotarod model was used to test the sedative qualities of these α_2 / imidazoline agonists in wild-type and α_{2ABC} -KO mice (figure 28). Following the baseline (untreated) measurement, clonidine, moxonidine and rilmenidine were each administered as a single ip dose of 50 μ g drug. Due to the high degree of sedation achieved in wild-type mice with the identical dose of medetomidine, both groups received only 25 μ g medetomidine. Fifteen minutes later, the time each mouse could still balance on the rotarod before falling off was determined; this time was expressed in percent of the untreated time. Clonidine greatly impaired the ability of wild-type mice to balance on the rotating rod, while moxonidine showed only a slight sedative effect. Rilmenidine had no significant effect on wild-type coordination. The “selective” α_2 -agonist medetomidine surpassed clonidine in its sedating effects, affirming its use as a veterinary tranquilizer. Mice deficient in all three α_2 -receptor subtypes were not hindered in their performance on the rotarod by any of the agonists, clearly demonstrating that the sedative properties of clonidine and moxonidine are indeed α_2 -mediated.

Fig. 28: Rotarod evaluation of the sedative properties of four α_2 -agonists with imidazoline (or imidazoline-like) structure. Each bar depicts the group mean balancing time on the rotarod following agonist injection, expressed in % of time on the rotarod prior to injection, \pm SEM. In wild-type mice, medetomidine showed the strongest sedative effect ($p < 0.0001$), followed by clonidine ($p = 0.017$) and, to a much lesser extent, moxonidine ($p = 0.049$). α_{2ABC} -KO mice displayed no impairment in their performance on the rotarod after agonist treatment. Statistical significance was determined using the two-tailed unpaired t test; $n=6$ per group.

2.2. Analgesia

The analgesic efficacy of clonidine is well established. If used prior to or during surgery, it may reduce the amount of anesthetic needed (Watanabe et al., 2006). In addition, the analgesic action of clonidine is independent of that of morphine and may complement the efficacy of opioid analgesics (Özdoğan et al., 2004). The long use of clonidine in surgery supports its safety and efficacy, and has contributed to its application in pediatric medicine (Bergendahl et al., 2006).

A tail-flick apparatus was used to assess the relative analgesic potencies of clonidine, moxonidine and rilmenidine in wild-type and α_{2ABC} -KO mice (figure 29). Each mouse received 50 μ g drug following the baseline (untreated) measurement. The time that passed until each mouse in a given group removed its tail from the thermal stimulus following agonist injection was determined and expressed in percent of the untreated time. Upon comparison of the group means, clonidine significantly increased pain threshold in wild-type mice. Moxonidine and rilmenidine did not appear to produce an analgesic effect in wild-type mice (n=6) under these conditions. None of the three drugs elicited any analgesic response in α_{2ABC} -KO mice. These results were not surprising, as previous findings have demonstrated the considerable contribution of the α_{2A} -subtype to the analgesic effect of clonidine (Lakhlani et al., 1997).

Fig. 29: Tail-flick assay to assess the analgesic potency of three α_2 -agonists in wild-type and α_{2ABC} -KO mice. Each bar depicts the group mean

time, expressed as % of mean baseline time, to remove tail from the thermal stimulus, \pm SEM. Of the three α_2 -agonists, only clonidine was capable of significantly increasing pain threshold in wild-type mice ($p = 0.0161$, $n=3$). Although moxonidine has previously been shown to decrease pain sensation in wild-type mice (Fairbanks and Wilcox, 1999), in this experimental design no significant effect of moxonidine or rilmenidine was observed ($n=6$). α_{2ABC} -KO mice ($n=7$) experienced no analgesic effect from any of these α_2 -agonists.

2.3. Glycemic response

Activation of α_2 -receptors in the pancreas directly inhibits insulin release. Therefore, administration of an α_2 -agonist to a wild-type mouse should lead to an acute hyperglycemic response within minutes. Plasma glucose concentration was determined for each mouse before and after agonist administration; the mean plasma glucose level of the respective group of mice at 30, 60 and 90 minutes was expressed in percent of the first measurement at $t = 0$, immediately prior to agonist injection (figure 30). Wild-type mice displayed significant increases in plasma glucose levels with moxonidine, clonidine and rilmenidine. In mice lacking all three α_2 -receptor subtypes, a significant hypoglycemic response only after clonidine administration was observed.

Fig. 30: Acute glycemic response to α_2 / imidazoline agonists in wild-type and α_{2ABC} -KO mice. a, 90 minutes after agonist injection, moxonidine

and clonidine elicited a highly significant hyperglycemic response in wild-type mice ($p < 0.001$); rilmenidine was slightly less effective ($p < 0.05$). **b**, In α_{2ABC} -KO mice only clonidine showed a significant hypoglycemic effect at $t = 90$ min ($p < 0.001$). The points on the curves represent the group mean \pm SEM of $n=6-8$ wild-type and $n=7-13$ α_{2ABC} -KO mice per group. Control mice (“no drug”) did not receive agonist injection, but blood was sampled at $t = 0, 30, 60$ and 90 min as with the mice receiving agonist. Statistical significance was determined by one-way ANOVA.

2.4. Cardiovascular effects

Blood pressure of anesthetized wild-type and α_{2ABC} -KO mice was monitored by catheterization of the femoral artery. Clonidine was administered via injection into a venous catheter. In wild-type mice, clonidine dose-dependently reduced diastolic and systolic blood pressure and heart rate (figure 31a). In contrast, no hypotensive effect could be observed after clonidine injection in α_{2ABC} -KO mice (figure 31b). However, heart rate of α_{2ABC} -KO mice was reduced by approximately 60 bpm after injection of $150 \mu\text{g}/\text{kg}$ clonidine (figure 31b).

Fig. 31: *In vivo* monitoring of α_2 / imidazoline agonist effects in anesthetized α_{2ABC} -KO mice. Shown are representative trace recordings of blood pressure and heart rate prior to and following administration of clonidine at doses of 10, 50 and 150 $\mu\text{g}/\text{kg}$ mouse body weight. No significant decrease in baseline blood pressure was observed in any of the α_{2ABC} -KOs tested after

clonidine treatment. However, heart rate in both groups did decrease in a dose-dependent manner, α_{2ABC} -KO heart rate albeit to a lesser extent.

To compensate for a possible influence of isoflurane anesthesia on these results, ECG sensors were transplanted into wild-type and α_{2ABC} -KO mice, allowing telemetric monitoring of heart rate in conscious, freely moving mice. These experiments were performed by Nadine Beetz and Lutz Hein at the University of Freiburg. Intraperitoneally-administered clonidine decreased resting heart rate in both groups in a dose-dependent manner (figure 32). Although the bradycardic response to clonidine was attenuated in α_{2ABC} -KO mice compared to wild-type mice, the α_2 -independent decrease in α_{2ABC} -KO heart rate nevertheless constituted 32%, 27% and 43% of the clonidine-induced bradycardia in wild-type mice at 10, 100 and 300 $\mu\text{g}/\text{kg}$, respectively.

Fig. 32: Systemic administration of clonidine in conscious wild-type and α_{2ABC} -KO mice. Similar to experiments conducted in anesthetized mice (figure 31), clonidine lowered resting heart rate to a lesser extent in mice lacking α_2 -receptors than in wild-type mice. In awake mice, the significance of the bradycardic effects of clonidine both within (* denotes $p < 0.05$) and between (#) the groups became apparent ($n=6-9$ mice per group). At the highest dose of 300 $\mu\text{g}/\text{kg}$ tested in both groups, over 40% of the bradycardia observed in α_{2ABC} -KO was α_2 -independent. n.d. = not determined.

3. Identification of the target protein(s) responsible for clonidine-induced bradycardia in α_{2ABC} -deficient mice

Clonidine was demonstrated to lower heart rate in both wild-type and α_{2ABC} -KO mice. While the bradycardic effect of clonidine was clearly less pronounced in α_{2ABC} -deficient mice than in wild-type, a considerable portion of the clonidine-induced decrease in heart rate could not be attributed to α_2 -receptors. To identify the target or targets of this bradycardic response to clonidine in α_{2ABC} -KO mice, it was next necessary to simplify the experimental system. In order to determine whether or not the clonidine effect on heart rate in the absence of α_2 -receptors was centrally-derived or peripheral in nature, an in vitro system was chosen.

3.1. Isolated spontaneously beating right atria

Organ bath experiments were performed to confirm the location of the bradycardic action of clonidine in α_{2ABC} -KO mice. The frequency of isolated, spontaneously beating right atria from α_{2ABC} -KO mice was reduced by 100 μM clonidine by approximately 50% of the beating frequency of wild-type right atria (figure 33), a proportion similar to that observed in conscious wild-type and α_{2ABC} -KO mice at 300 $\mu\text{g}/\text{kg}$ clonidine (figure 32). This indicated that the origin of the bradycardic response was in the atrium itself. Organ bath experiments with isolated spontaneously beating right atria yielded clonidine dose-response curves in wild-type and α_{2ABC} -KO right atria with similar IC_{50} values in both genotypes (6.2 μM and 4.8 μM , respectively).

Fig. 33: *Decrease in spontaneous beating frequency with clonidine in isolated right atria from wild-type and α_{2ABC} -KO mice. Clonidine lowered*

spontaneous beating frequency in wild-type ($n=6$) and β_{2ABC} -KO ($n=7$) right atria with similar affinity (IC_{50} wild-type: $6.2 \mu\text{M}$, IC_{50} β_{2ABC} -KO: $4.8 \mu\text{M}$). The points on the curves represent the group mean \pm SEM of the beating frequency, expressed as percent of baseline beating frequency, at the respective clonidine concentration.

After localization of the β_2 -independent decrease in spontaneous beating frequency induced by clonidine, various antagonists and inhibitors were tested in an attempt to interfere with this effect in β_{2ABC} -KO atria (table 2).

antagonist / inhibitor	target
pertussis toxin	G_i proteins
Ba^{2+} (100 μM)	inward rectifier K^+ channels
Cs^+ (2mM)	most K^+ channels
ZD 7288	HCN channels

Tab. 2: Antagonists and inhibitors of some atrial regulators of heart rate. These substances were tested for their potential to interact with the bradycardic effect of clonidine in isolated right atria.

Pertussis toxin (PTX), an unselective inhibitor of G_i proteins, failed to abolish or even reduce the bradycardic effect of clonidine in the right atria of β_{2ABC} -KO mice when injected 16 hours prior to sacrifice (figure 34). The administered dose of PTX was sufficient to eliminate the M2-muscarinic receptor-mediated reduction in beating frequency by the agonist carbachol in pretreated β_{2ABC} -KO mice (figure 34). The right atrial beating frequency of PTX-untreated β_{2ABC} -KO mice was further decreased with carbachol following clonidine administration, suggesting that clonidine did not interact with muscarinic receptors. These results eliminated the involvement of G_i -coupled receptors in the bradycardic action of clonidine. As no G_s - or G_q -coupled receptors could explain the β_2 -independent decrease in beating frequency, the possible influence of clonidine on ion currents was next examined.

Fig. 34: The bradycardic effect of clonidine in α_{2ABC} -KO mice is not dependent on G_i proteins. Right atrial frequency, expressed in % of control (baseline), of α_{2ABC} -KO mice either untreated or injected 16 h prior to the organ bath experiment with 150 μ g/kg pertussis toxin (PTX) ip. Bars depict the mean \pm SEM of untreated ($n=4$) and PTX-treated ($n=4$) α_{2ABC} -KO mice before (= control) and after addition of clonidine, and – after rinsing – of carbachol to the organ bath. Pretreatment with PTX did not diminish the bradycardic effect of clonidine (* $p < 0.05$ untreated vs. control, ** $p < 0.001$ treated vs. control; one-way ANOVA). However, PTX did abolish the ability of carbachol to lower frequency in spontaneously beating right atria.

In the right atrium, Ca^{2+} and K^+ currents are primarily responsible for generation of heart beat (see Introduction, chapter 1.2.2., Heart rate). Figure 35 illustrates the consequences of K^+ current inhibition by Ba^{2+} and Cs^+ on the reduction of beating frequency by clonidine. The addition of 100 μ M Ba^{2+} to the bath fluid did not suppress atrial response to clonidine, excluding the involvement of inward rectifier K^+ channels, as these were effectively blocked by Ba^{2+} at this concentration (Stelling and Jacob, 1992). In contrast, Cs^+ , which blocks most K^+ channels but also pacemaker channels as well (Levick, 1998), completely abolished the clonidine-mediated bradycardia. This was the first substantial evidence in support of pacemaker channels, more precisely known as HCN (hyperpolarization activated, cyclic nucleotide-gated cation) channels, as a non- α_2 molecular target of clonidine.

Fig. 35: α_{2ABC} -KO right atrial frequency in the presence of Ba^{2+} or Cs^{+} . Black bars show the mean % change in control frequency \pm SEM after addition of clonidine to $n=6$ right atria in Ba^{2+} -containing solution and to $n=5$ in Cs^{+} containing bath. Ba^{2+} did not affect the ability of clonidine to lower frequency ($p = 0.0025$, two-tailed unpaired t test), while the presence of Cs^{+} completely abolished the clonidine effect.

The specific HCN channel blocker ZD 7288 (BoSmith et al., 1993) prevented a further reduction in beating frequency by clonidine. 10 μ M ZD 7288 slowly but significantly lowered beating frequency in α_{2ABC} -KO right atria (figure 36). When clonidine was added to the bath, the frequency remained significantly lower than control, but was indistinguishable from that in the presence of ZD 7288 alone. Addition of 1 μ M isoproterenol failed to elevate beating frequency, as HCN channels mediate the effect of increased sympathetic tone on beating frequency (Levick 1998). As proposed by a previous experiment where clonidine inhibited the neuronal I_h current in isolated sciatic nerve, this suggests that clonidine and ZD 7288 may share a common site of action (Kroin et al., 2004).

Fig. 36: Inhibition of cardiac HCN channels prevents the bradycardic effect of clonidine in β_{2ABC} -KO right atria. Bars represent the mean right atrial frequency in % of control \pm SEM after addition of 10 μ M ZD 7288 and after 100 μ M clonidine to the bath solution of $n=6$ right atria. Clonidine did not lower the beating frequency of β_{2ABC} -KO right atria after pretreatment with the specific HCN channel blocker ZD 7288. Isoproterenol failed to raise frequency in the presence of ZD 7288 and clonidine ($n=3$ atria). Both ZD 7288 and clonidine lowered frequency significantly from control ($p < 0.001$; one-way ANOVA); however, none of the three bars differed significantly from each other (two-tailed unpaired t test).

3.2. [3 H]Clonidine binding in β_{2ABC} -KO membranes

Competition binding with ZD 7288 was performed in β_{2ABC} -KO heart membranes to assess whether or not the specific HCN inhibitor interacted with the [3 H]clonidine binding site identified in β_{2ABC} -KO tissues. Surprisingly, the competition curves of ZD 7288 and clonidine in the presence of 8 nM [3 H]clonidine nearly overlapped (figure 37).

Fig. 37: Displacement of [³H]clonidine (8 nM) binding by the specific HCN blocker ZD 7288 in α_{2ABC} -KO heart membranes. Binding curves were fit using the one-site competition model. Each symbol depicts the mean of 9 measurements from three experiments performed in triplicate, \pm SEM. Clonidine showed an IC_{50} value of approximately 0.5 μ M, while ZD 7288 displayed a very similar IC_{50} value of 0.3 μ M.

3.3. Effect of clonidine in stably transfected HEK293 cells

In order to test the potential interaction of clonidine with HCN channels, electrophysiological measurements were performed by Dr. Xiangang Zong and Prof. Martin Biel in Munich. HEK293 cells stably expressing the (murine) HCN1, (murine) HCN2 and (human) HCN4 subtypes were chosen to substantiate the interaction of clonidine with pacemaker channels observed in vitro. Electrophysiological measurements indisputably showed a decrease in I_f current upon clonidine administration. Whole-cell patch clamp recordings revealed a dose-dependent reduction of pacemaker current with increasing clonidine concentration from 1 μ M to 1 mM (figure 38). The resulting inhibition curve yielded an IC_{50} value in the low micromolar range.

Fig. 38: Clonidine inhibits the HCN2 channel in a concentration-dependent manner. Figure 38a depicts a representative recording for clonidine inhibition of HCN2 obtained by whole-cell patch clamp recording of stably transfected HEK cells. At time 0, no clonidine was present and the basal I_f current was apparent. Increasing concentrations of clonidine – 1 μM , 10 μM and 300 μM – continually suppressed the I_f current until it was completely blocked at the highest clonidine concentration. **b**, In HCN2-stably expressing HEK cells, clonidine inhibited the HCN2 subtype with an IC_{50} value of 7.15 μM . Measurements and diagrams were kindly provided by Dr. Xiangang Zong and Prof. Martin Biel from the Ludwig-Maximilians Universität in Munich, Department of Pharmacy.

Analogous experiments were conducted in HEK cells stably expressing the HCN1 and HCN4 subtypes. The IC_{50} value of clonidine for the HCN4 subtype, the predominant subtype in sinoatrial node cells (Ishii et al., 1999), was nearly identical to that of the HCN2 subtype (9.7 μM vs. 7.2 μM , respectively). Clonidine affinity to the HCN1 subtype was 4-6 fold lower (42 μM) as compared with HCN2 and HCN4 (table 3).

HCN channel subtype	IC_{50} clonidine
HCN1	42 μM
HCN2	7.2 μM
HCN4	9.7 μM

Tab. 3: IC_{50} values of clonidine for the HCN channel subtypes HCN1, HCN2 and HCN4. Clonidine blocked HCN2 and HCN4 channel subtypes with nearly equal potency ($IC_{50} < 10 \mu\text{M}$), while the affinity for the HCN1 subtype was slightly lower (42 μM). Data were kindly provided by Dr. Xiangang Zong and Prof. Martin Biel, Munich.

3.4. Effect of clonidine in cultured isolated sinoatrial node cells

After the clonidine-mediated inhibition of HCN channel subtypes was well established in stably transfected HEK cells, it was necessary to test whether or not this occurred in the atrium. The I_f current from the sinoatrial node (SAN) cells isolated from both wild-type and $\alpha_2\text{ABC-KO}$ mice was measured using the whole-cell voltage clamp technique. Clonidine reduced the I_f current dose-dependently in both wild-type and $\alpha_2\text{ABC-KO}$ SAN cells (individual traces not shown). This inhibition was nearly identical in both genotypes, as the clonidine dose-response curves generated from these measurements nearly overlapped (figure 39). The IC_{50} values from the SAN cells (approximately $3 \mu\text{M}$ in both genotypes) were in accordance with those from stably transfected HEK cells ($\text{IC}_{50}[\text{HCN4}] = 9.7 \mu\text{M}$, table 3).

Fig. 39: Clonidine inhibition curves in SAN cells. Clonidine inhibited HCN channels in isolated SAN cells from $\alpha_2\text{ABC-KO}$ mice with the same affinity and potency as in wild-type SAN cells. The resulting inhibition curve from n (the number in parenthesis) recordings is shown. The points on the two curves express the mean and SEM of n values. Data were kindly provided by Dr. Xiangang Zong and Prof. Martin Biel, Munich.

Once it was established that clonidine indeed inhibited the I_f current in the sinus node, the question arose as to the mechanism by which it interacted with the HCN channels. To demonstrate the link between clonidine-induced I_f inhibition and bradycardia in $\alpha_2\text{ABC-KO}$ mice, the perforated patch technique with amphotericin B was used to measure spontaneous action potentials of wild-type and $\alpha_2\text{ABC-KO}$ SAN cells (figure 40a, 40b).

Fig. 40: Action potential recordings in SAN cells from wild-type and α_{2ABC} -KO mice. In both genotypes, clonidine evoked a marked increase in cycle length, or the time between two consecutive action potentials. Inhibition of the I_f current was evidenced by a delay in return to threshold potential following clonidine treatment. The action potential duration during systole remained unchanged after clonidine. Data were kindly provided by Dr. Xiangang Zong and Prof. Martin Biel, Munich.

Analysis of the individual components of the action potential provided much insight (table 4). As demonstrated by the recorded spontaneous action potentials in the previous figure, the cycle length in SAN cells from both wild-type and α_{2ABC} -KO mice was significantly increased with clonidine. This appeared to be mainly, if not exclusively, due to a decrease in the speed of diastolic depolarization, as all other measured parameters remained unchanged. While the proportional decrease of diastolic depolarization by clonidine was equal in wild-type and α_{2ABC} -KO SANs (approximately 55%), cycle length was increased by a much higher percentage in wild-type (ca. 240%) than compared to α_{2ABC} -KO (ca. 150%).

parameter	$\square_{2ABC}^{+/+}$		$\square_{2ABC}^{-/-}$	
	control (n)	clonidine	control (n)	clonidine
CL [ms]	455 \pm 48 (6)	1105 \pm 223*	605 \pm 45 (4)	895 \pm 98*
DD [mV/s]	79.7 \pm 8.1 (6)	45.6 \pm 6.6*	62.1 \pm 9.9 (4)	34.1 \pm 7.9*
RP [mV]	-56.7 \pm 1.5 (6)	-57.8 \pm 2.1	-58.4 \pm 1.2 (4)	-58.9 \pm 1.0
OS [mV]	18.2 \pm 3.5 (6)	18.2 \pm 3.6	17.5 \pm 2.4 (4)	18.2 \pm 3.8
APD50 [ms]	68.7 \pm 14 (6)	67.7 \pm 11.9	72.6 \pm 20.7 (4)	70.0 \pm 20.6
APD90 [ms]	116 \pm 17.8 (6)	118 \pm 14.8	129 \pm 21.6 (4)	130 \pm 20.2

Tab. 4: Effects of clonidine on various action potential parameters in isolated SAN cells from wild-type and \square_{2ABC} -KO mice. Clonidine significantly increased the time between two consecutive action potentials (cycle length) by decreasing the speed with which membrane potential returned to threshold potential (diastolic depolarization). Significant changes ($p < 0.05$) from baseline are denoted with an asterisk *. CL: cycle length; DD: diastolic depolarization; RP: resting potential; OS: overshoot; APD50 and APD90: 50% and 90% of the action potential duration. Data were kindly provided by Dr. Xiangang Zong and Prof. Martin Biel, Munich.

3.5. Effect of moxonidine in stably transfected HEK293 cells

The mixed \square_2 / imidazoline agonist moxonidine was evaluated to determine whether it showed similar effects on HCN channels as clonidine. Application of 50 μ M moxonidine failed to significantly lower I_f current in HEK293 cells expressing either the HCN2 (figure 41a) or the HCN1 (figure 41b) subtype. Clonidine administration (50 μ M) following moxonidine decreased I_f current as observed previously. This finding correlated well with in vivo heart rate measurements in anesthetized \square_{2ABC} -KO mice, where moxonidine only slightly lowered the frequency of the beating heart.

Fig. 41: Moxonidine does not inhibit HCN1 and HCN2 channel subtypes. The effects of identical concentrations of moxonidine and clonidine on HEK293 cells stably transfected with murine HCN2 (a) and HCN1 (b) channels were determined by whole-cell voltage clamp measurement. Moxonidine showed no significant inhibition of either HCN1 or HCN2 channel subtype. Data were kindly provided by Dr. Xiangang Zong and Prof. Martin Biel, Munich.

VI. Discussion

Prior to the generation of α_2 -deficient mice, it was very difficult to assign a particular physiological role to a specific α_2 -subtype with much certainty. No α_2 -ligands with sufficient subtype specificity were available, and, as two or all three α_2 -subtypes are often expressed together, it was not always possible to infer function unique to one subtype based merely on its (sub)cellular location. α_2 -deficient mice presented an opportunity to examine each subtype in the absence of the remaining subtype(s). Not until this powerful tool was available did it become clear, for example, that each α_2 -subtype played a distinct role in the modulation of norepinephrine release (Hein et al., 1999; Trendelenburg et al., 2003).

1. Analysis of α_{2ABC} -deficient mice

Equally intriguing were the characteristics displayed in α_{2ABC} -deficient mice. Although at first the generation of this line did not appear feasible due to the extremely high embryonic lethality (less than 1 of 250 embryos survived until birth), over time enough α_{2ABC} -KO survivors were recovered to establish a breeding colony. The mixed genetic background of these founding mice apparently compensated for the insufficient placental vascularization due to deletion of the α_{2B} -subtype in congenic mice (Philipp et al., 2002c).

The complete absence of α_2 -receptors was verified both on a molecular as well as on a functional level. Routine PCR genotyping (figure 13) as well as initial Southern blotting concurrent with the generation of α_2 -single KOs (Philipp et al., 2002c) confirmed the insertion of the neomycin resistance cassette into the coding region of each α_2 -subtype, rendering all three α_2 -receptor genes nonfunctional. Radioligand binding both in whole brain slices as well as in brain membrane preparations with the selective α_2 -antagonist [3 H]RX 821002 failed to detect any specific binding in α_{2ABC} -KO brain, analogous to that observed in wild-type brain in the presence of the α_2 -antagonist atipamezole at saturating levels (figure 14d). The lack of presynaptic control by α_2 -autoreceptors was manifest by the inability of norepinephrine to suppress the release of [3 H]norepinephrine following electrical stimulation of α_{2ABC} -KO atrial tissue (figure 18). Dysregulated

sympathetic activity in α_{2ABC} -KO mice was also evident by elevated norepinephrine levels in α_{2ABC} -KO urine (figure 19). The deleterious consequences of absent negative feedback control and resulting elevated catecholamine levels later became visible at both a microscopic level (fibrosis and hypertrophy of left ventricular myocytes, figures 24-26) and at a functional level as well (impaired shortening fraction, figure 27).

2. Mechanisms of action of clonidine and clonidine-like drugs

There is still much controversy as to the exact mechanism by which clonidine and similar α_2 -agonists possessing an imidazoline structure lower blood pressure. The older α_2 -hypothesis, which attributes the antihypertensive effect of clonidine to α_2 -receptors alone (van Zwieten et al., 1984; Guyenet, 1997), has lost ground to the newer imidazoline hypothesis. This hypothesis was originally proposed by Bousquet and colleagues after the observation that many α_1 / α_2 -imidazoline-containing ligands were able to lower blood pressure when microinjected into the rostral ventrolateral medulla (Bousquet et al., 1984). The specificity for α_1 - or α_2 -adrenergic receptors appeared to play less of a role in the ligand's ability to centrally inhibit sympathetic tone; crucial, however, seemed the presence of an imidazoline moiety, as this effect was not observed when catecholamine α -adrenergic ligands were injected into the same brainstem region (Ernsberger and Haxhiu, 1997). While the existence of this central imidazoline "receptor" is generally recognized today, there is still an ongoing debate as to whether it alone is responsible for the sympathoinhibitory (and therefore therapeutic) effects of clonidine and clonidine-like antihypertensives, or if the imidazoline I_1 -binding site is merely that, with no physiological importance. In addition to its antihypertensive effect, clonidine lowers heart rate as well. Clonidine-elicited bradycardia is ascribed to its stimulation of presynaptic α_2 -autoreceptors, thereby reducing sympathetic activity (van Zwieten et al., 1984).

Outside of the cardiovascular system, clonidine is known for its strong sedative properties. This unwanted "side" effect of daily antihypertensive treatment likely spurred the search for α_2 / I_1 imidazoline agonists with less pronounced sedative effects. While moxonidine and rilmenidine have been shown to be less sedating, there is disagreement as to how much less pronounced this side effect is compared to with clonidine. These differences in amount of sedation have been attributed to the higher affinities of moxonidine and rilmenidine to I_1 binding sites (Szabo, 2002). When clonidine is used as a pre- or post-operative sedative, the additional analgesic properties of this drug are desirable.

Mice lacking all three α_2 -receptor subtypes were an ideal model with which to test the validity of the imidazoline hypothesis. If indeed imidazoline I_1 -binding sites are physiologically functional and independent of α_2 -adrenergic receptors, a similar, although perhaps diminished, effect of clonidine and other centrally acting antihypertensives would be expected in α_{2ABC} -KO mice compared to in wild-type mice. The absence of sympathetic inhibition in these mice after drug administration could be interpreted in two ways: either I_1 -binding sites are unable to evoke a physiological response (Munk et al., 1996), or they are only functional in the presence of α_2 -receptors, acting - in a manner not yet understood - in cooperation with them (Bruban et al., 2002).

3. Cardiovascular effects of clonidine in α_{2ABC} -deficient mice

The effects of clonidine on blood pressure and heart rate in α_{2ABC} -KO mice were observed. In anesthetized α_{2ABC} -KO mice, the femoral artery was chosen for catheter insertion for blood pressure measurement, as insertion and vessel constriction at this location were much less likely to disturb the baroflex than in the carotid artery. Not only clonidine (figure 31), but moxonidine and rilmenidine as well (not shown) failed to significantly decrease mean arterial pressure in α_{2ABC} -KO mice. Since clonidine was observed to significantly lower heart rate in α_{2ABC} -KOs as well as in wild-type mice, this drug was studied more closely, and the effects at different doses were assessed in both groups of mice. Even at doses as high as 150 $\mu\text{g}/\text{kg}$, clonidine failed to show any hypotensive effect in the absence of α_2 -receptors. These results are in good agreement with those from previous studies examining the hypotensive effect of α_2 -agonists in mice deficient in functional α_{2A} -receptors, due either to point mutation – D79N α_{2A} -mutant (MacMillan et al., 1996; Zhu et al., 1999) – or to deletion – α_{2A} -KO (Altman et al., 1999). Taken together, these findings substantiate that the presence of functional α_2 -receptors is indeed required for these α_2 / imidazoline agonists to lower blood pressure (Szabo, 2002).

Despite its failure to lower blood pressure, clonidine did markedly decrease heart rate in anesthetized α_{2ABC} -KOs. This bradycardic effect was much less pronounced with moxonidine; rilmenidine did not appear to influence heart rate at all (not shown). In conscious, unrestrained wild-type and α_{2ABC} -KO mice monitored via telemetry, clonidine again produced a dose-dependent decrease in baseline heart rate in the absence of α_2 -receptors. At the highest clonidine dose in both groups (300 $\mu\text{g}/\text{kg}$ in conscious mice), clonidine lowered baseline heart rate by 50% in wild-type and by approximately 25% in α_{2ABC} -KO mice (figure 32). While α_2 -receptors clearly played the predominant

role in the clonidine-induced bradycardia, the substantial contribution of a non- α_2 -adrenergic target of clonidine was unmistakable.

4. Other effects of clonidine in α_{2ABC} -deficient mice

Activation of α_2 -receptors in the pancreas indirectly regulates the release of insulin into the blood stream via $G_{i/o}$ -mediated inhibition of adenylyl cyclase and reduction of intracellular Ca^{2+} levels, thereby inhibiting Ca^{2+} sensitive $K^+(ATP)$ channels which control the exocytotic release of insulin (Ullrich and Wollheim, 1985; Hsu et al., 1991). As expected, clonidine evoked an immediate increase in plasma glucose in wild-type mice (figure 30). In contrast, α_{2ABC} -KO mice responded to clonidine application with a mild but significant decrease in plasma glucose levels. Moxonidine and rilmenidine did not appear to elicit a hypoglycemic response in α_{2ABC} -KO mice; medetomidine displayed absolutely no effect in α_{2ABC} -KOs (Lee et al., 1995). Some imidazoline-containing compounds, such as efaroxan, are known to stimulate insulin secretion due at least in part to interaction with the Kir6.2 pore component of the $K^+(ATP)$ channel via an I_3 imidazoline binding site (Morgan and Chan, 2001). While this may provide an explanation for the hypoglycemic action of clonidine in α_{2ABC} -KO mice, its confirmation is beyond the scope of this project.

Sedation and analgesia are two well known properties of clonidine that have long been recognized to be mediated by α_2 -adrenergic receptors (van Zwieten et al., 1984; Correa-Sales et al., 1992). Studies with α_{2A} -deficient mice have demonstrated that this subtype plays the predominant role in clonidine-induced elevation of pain threshold (Özdoğan et al., 2004, Röser, 2005). As expected, clonidine failed to produce either a sedative or an analgesic effect in α_{2ABC} -KO mice (figures 28-29). Although both drugs elicited significant effects in wild-type mice, clonidine was a far more potent sedative and analgesic than moxonidine. While differences in α_2 and I_1 affinities could explain the lack of “side effects” with moxonidine, perhaps another explanation contributes to this observation as well. In spontaneously hypertensive rats, clonidine was found to be 10-fold more potent than moxonidine in lowering blood pressure (Ernsberger et al., 1997). As both drugs produced an equal antihypertensive response at identical doses when microinjected into the RVLM, the authors attributed the lower potency of peripherally applied moxonidine to a lesser degree of penetration of the blood-brain barrier than clonidine. A lower lipophilicity of moxonidine could well account for both the lack of analgesic response, as well as the greatly reduced sedation, with moxonidine compared to with clonidine in wild-type mice in this study. Many of the experiments confirming the analgesic potency of moxonidine are performed via intrathecal

injection of moxonidine, thereby circumventing the blood-brain barrier and offering a possible explanation for this discrepancy.

5. Bradycardic effect of clonidine in α_{2ABC} -deficient mice is mediated by inhibition of pacemaker (HCN) channels

After establishing the bradycardic effect of clonidine in α_{2ABC} -KO mice, we turned to in vitro experiments to pinpoint the target(s) of this action. Organ bath experiments with spontaneously beating wild-type and α_{2ABC} -KO right atria confirmed in vivo findings and narrowed the location of the molecular target(s) of clonidine to the right atrium. Clonidine dose-dependently decreased spontaneous beating frequency in wild-type and α_{2ABC} -KO right atria with nearly equal affinity. Assuming that the entire clonidine dose is retained in the plasma, a rough estimate of the clonidine concentration after administration of 300 $\mu\text{g}/\text{kg}$ clonidine to a 30 g mouse with 2.4 ml blood volume (Mitruka and Rawnsley, 1981; Harkness and Wagner, 1989) is approximately 14 μM . This value is well within range of the higher clonidine concentrations used in organ bath experiments and further confirms that this indeed is the molecular target mediating the bradycardia induced by clonidine in α_{2ABC} -KO mice.

Next, antagonists and inhibitors of likely candidates for this non- α_2 target of clonidine were tested (table 2). Pretreatment of α_{2ABC} -KO mice with pertussis toxin to inactivate $G_{i/o}$ proteins did not diminish the decrease in spontaneous beating frequency by clonidine in isolated α_{2ABC} -KO atria, therefore excluding all G_i protein coupled receptors as possible targets (figure 34). Although many ion channels (particularly K^+ channels) contribute to pacemaker activity in the right atria, three major regulators of action potential predominate. L-type Ca^{2+} channels generate the I_{CaL} current, regarded as the most important pacemaker current, as the I_{CaL} channel threshold potential is nearly the same as that of the pacemaker potential of SAN cells (Satoh, 2003). T-type Ca^{2+} channels play only an insignificant role in maintaining the pacemaker current. Diltiazem and mibefradil, inhibitors of L-type and T-type Ca^{2+} currents, respectively, did not interfere with clonidine-induced reduction of beating frequency when added to the bath (not shown). Ba^{2+} is a known inhibitor of delayed rectifier K^+ channels which are responsible for repolarization and return to resting potential (Satoh, 2003). Ba^{2+} , too, failed to influence the effect of clonidine (figure 35). The pacemaker, or I_f , current is characteristic of SAN cells. The pacemaker HCN channel is both K^+ and Na^+ permeable, depolarizing slowly until threshold potential is reached (DiFrancesco, 1981). Other K^+ channels play lesser roles in the regulation of pacemaker activity. Many K^+ channels, including HCN channels, are inhibited by Cs^+ (Levick, 1998). In the presence of 2 mM Cs^+ ,

clonidine was no longer able to lower the beating frequency of β_{2ABC} -KO atria (figure 35). In addition, after incubation with the specific HCN channel inhibitor ZD 7288 (BoSmith et al., 1993), clonidine did not (further) reduce the frequency of spontaneously beating β_{2ABC} -KO right atria (figure 36). Two previous studies have indicated that clonidine inhibited the I_h current (the I_f current equivalent in neurons) in both rat sciatic nerve (Kroin et al., 2004) and in desheathed rabbit vagus nerve (Dalle et al., 2001); this inhibition was presumed to be at least partly responsible for the analgesic prolongation of local anesthetics, such as lidocaine, when clonidine was added (Dalle et al., 2001). The interaction between ZD 7288 and clonidine described above is similar to that of Kroin and colleagues (2004), who demonstrated that clonidine was not able to further lower I_h in sciatic nerve pretreated with ZD 7288, suggesting a common site of action.

To confirm that HCN channels were indeed directly targeted by clonidine, we then began a collaboration with Dr. Xiangang Zong and Prof. Dr. Martin Biel at the Ludwig-Maximilians-Universität in Munich, in whose group the HCN channels were originally cloned and molecularly characterized (Ludwig et al., 1998; see also Santoro et al., 1998). In HEK293 cells stably transfected with HCN subtypes HCN1, HCN2 and HCN4, as well as in sinoatrial node (SAN) cells isolated from wild-type and β_{2ABC} -KO mice, clonidine directly inhibited HCN currents (figures 38-39). Clonidine displayed equal affinity and potency for HCN channels in SAN cells from both groups of mice. In contrast, moxonidine failed to inhibit recombinant HCN channels expressed in HEK293 cells (figure 41). Of all the parameters contributing to cycle length in isolated SAN cells, only diastolic depolarization was significantly decreased (table 4). These results are consistent with a previous study of the effects of clonidine and moxonidine in rabbit SAN cells. In tissue strips excised from the sinoatrial node region of rabbit right atrium, both drugs (0.1 mM – 30 mM) decreased rate of pacemaker firing and increased cycle length; however, preincubation with yohimbine completely blocked the effects of moxonidine but only partially blocked those of clonidine (Zhao and Ren, 2003). The authors concluded that while moxonidine decreased pacemaker activity via β_2 -receptors alone, clonidine lowered rate of pacemaker firing via an unidentified β_2 -independent target as well.

6. No evidence for involvement of I_f binding sites in the bradycardic action of clonidine

Although saturation binding experiments revealed a non- β_2 high affinity binding site for [3 H]clonidine in β_{2ABC} -KO mouse membranes with a similar affinity to that of clonidine for the purported I_f binding site (Szabo, 2002),

characterization of this non- α_2 binding site during competition binding with other high affinity I_1 ligands did not support the equivalence of these two binding sites. The imidazoline hypothesis evolved around the binding properties of clonidine and its derivatives [^3H]p-aminoclonidine and [^3H]p-iodoclonidine (Dontenwill et al., 1999). Clonidine was reported to possess affinity to both α_2 -receptors and I_1 binding sites in the low nanomolar range (Bousquet et al., 2003). The newer, centrally acting antihypertensives moxonidine and rilmenidine are characterized by their higher affinity to I_1 binding sites than to α_2 -receptors (Bousquet and Feldman, 1999). The precise affinities of these drugs vary, sometimes greatly, depending on the tissue type and species from which the tissue was taken (Szabo, 2002). Moxonidine was found to be 70-fold more selective for I_1 sites than α_2 in bovine ventrolateral medulla membranes (Ernsberger et al., 1993), the tissue in which the I_1 site was originally studied. Yet other studies reported a nearly equal I_1 / α_2 affinity for moxonidine (Szabo, 2002); one study failed to find any I_1 affinity for moxonidine (Bricca et al., 1994). One binding study in cattle brain stem reported a 30fold higher affinity of rilmenidine for I_1 receptors compared to α_2 -receptors (Ernsberger et al., 1993); however, other studies could not substantiate the low nanomolar affinity determined previously (Szabo, 2002). In summary, numerous binding studies have been performed in support of I_1 binding sites, yet the evidence confirming the existence and nature of these sites has been weakened by conflicting results (Szabo, 2002). Since no uniform binding characteristics of the I_1 site are clearly defined, it is not possible to compare the non- α_2 binding site found in α_{2ABC} -KO mouse membranes with the purported I_1 site with any certainty. Considering the nonconformity of several of the tested “selective” imidazoline I_1 ligands (moxonidine, efaroxan, cimetidine and agmatine) to [^3H]clonidine binding in α_{2ABC} -KO mouse membranes, it seems highly unlikely this non- α_2 binding site is identical or even related to the purported I_1 site.

Not only were the binding characteristics of these two sites incongruous; the pharmacological effects of the α_2 / I_1 agonist clonidine in α_{2ABC} -KO mice were not in accordance with the purported actions of clonidine at the I_1 receptor (Bousquet, 2001). Clonidine failed to lower blood pressure in α_{2ABC} -deficient mice in several experimental settings (Results, 2.4.). While this could have been attributed to an insufficient concentration of clonidine in the rostral ventrolateral medulla (RVLM) after systemic application, other central effects such as sedation and analgesia were clearly visible in wild-type mice after identical doses of clonidine. At the highest clonidine doses administered, no change in blood pressure was observed (figure 31); most likely these clonidine doses were sufficient to achieve a nanomolar concentration in the RVLM necessary for activation of I_1 receptors. Taken together, our findings do not support the involvement of I_1 binding sites in the hypotensive effect of

clonidine and clonidine-like agonists. If indeed these sites do play a physiological role in the pharmacological action of these drugs, then it appears they do so only in concert with α_2 -receptors, as suggested by Dontenwill and colleagues (1999). Or perhaps these I_1 binding sites are devoid of any physiological effect, as was proposed by the group of Munk et al., the creators of a high-affinity I_1 -ligand which showed neither agonistic nor antagonistic properties in animals tested (1996).

Clonidine-induced bradycardia has been shown to result from both a reduction in sympathetic tone as well as an increase in vagal activity and consequent baroreceptor activation (Tangri et al., 1974). α_2 -adrenergic receptors in the nucleus tractus solitarius were later demonstrated to be required for activation of the baroflex (Sved et al., 1992). I_1 receptors do not appear to contribute to the heart rate lowering effects of clonidine, moxonidine and rilmenidine. No presynaptic I_1 binding sites have been identified on sympathetic nerve endings (Göthert et al., 1999). In addition, clonidine and moxonidine did not inhibit [3 H]norepinephrine release in the presence of the irreversible α_2 -antagonist phenoxybenzamine (Schlicker et al., 1997). α_2 -receptors have repeatedly been shown to moderate sympathetic tone, offering the most plausible explanation for the bradycardic action of these centrally acting antihypertensives (Szabo et al., 2001).

7. Therapeutic consequences of HCN blockade in human patients

Clonidine reduced the action potential frequency in mice by decreasing the speed of diastolic depolarization. However, it is not certain to what extent – if at all – clonidine lowers heart rate in humans via inhibition of HCN channels. The affinity of clonidine for the human HCN4 subtype expressed in HEK cells (IC_{50} = ca. 10 μ M) was in the same range as the IC_{50} value of clonidine determined in isolated mouse SAN cells (IC_{50} = ca. 3 μ M), where the HCN4 subtype predominates in both humans and mice (Ishii et al., 1999).

Assuming that the affinities of clonidine for recombinant HCN subtypes in HEK293 cells as well as for native HCN channels in murine SAN cells are similar to those for human HCN channels, the plasma concentration attained following a typical antihypertensive dose of clonidine (150 – 900 μ g/day) in humans (Onesti et al., 1971) would not be likely to inhibit HCN channels. Chronic administration of 75 μ g clonidine twice daily was shown to correspond to a maximum plasma concentration of 0.66 ± 0.06 ng/ml clonidine (Anavekar et al., 1989); another study with 300 μ g oral clonidine determined a peak plasma concentration of 1.34 ± 0.28 ng/ml in hypertensive patients (Wing et al., 1977). Although the hypotensive effect of clonidine has been shown to

diminish at plasma levels greater than 1.5 ng/ml (Wing et al., 1977; Frisk-Holmberg et al., 1984), higher clonidine plasma concentrations are not uncommon when used as an analgesic (Bernard et al., 1995). Patients self-administering iv clonidine attained a peak plasma concentration of 2.5 ± 0.6 ng/ml (Bernard et al., 1995). However, even in the highest therapeutic range clonidine concentration in human plasma remains below 10 nM, approximately a thousand fold less than the IC_{50} value of clonidine determined in isolated murine SAN cells. Therefore, the bradycardic effect of clonidine in human patients appears to be solely α_2 -mediated. This does not, however, exclude the possibility that bolus iv injection of clonidine during hypertensive emergency or rapid opioid detoxification may result in transiently elevated plasma concentrations sufficient to inhibit cardiac HCN channels in humans (Kienbaum et al., 2002).

The comparison of I_f inhibition by clonidine and that of a new class of selective I_f current inhibitors, the bradines, does however support the possibility of the contribution of this action to the bradycardic effect of clonidine in humans. To date, only ivabradine has been approved for the symptomatic treatment of patients with stable angina and who have a contraindication for β -blockers (Servier, 2006). Ivabradine provides an attractive alternative for the symptomatic treatment of ischemic heart disease without the decrease in blood pressure and cardiac contractility associated with β -blockers and Ca^{2+} channel blockers (Vilaine, 2006). Not only does the reduction in heart rate reduce the frequency of ischemic episodes (Borer et al., 2003), but it reduces the mortality associated with an increased heart rate as well (DiFrancesco and Camm, 2004). Therapeutic doses in humans range from 7.5 mg – 10 mg ivabradine, divided into two doses daily (Tardif et al., 2005). In mice, however, the EC_{50} value of ivabradine is nearly 5 mg/kg (Stieber et al., 2006). In contrast, clonidine reduced baseline heart rate in α_{2ABC} -KO mice by almost 50% at doses between 100 μ g/kg – 300 μ g/kg (figure 32). If the same discrepancy in the effective concentration between humans and mice exists for clonidine as is the case with ivabradine, then human HCN channels may indeed be (at least partially) inhibited at therapeutic plasma concentrations during antihypertensive treatment with clonidine.

8. Conclusion

In conclusion, clonidine was shown to directly inhibit cardiac HCN pacemaker channels in mice. It is not certain whether this may contribute to its strong bradycardic effect in humans. While the α_2 -mediated reduction of sympathetic tone is inarguably the predominant bradycardic mechanism of clonidine, a possible direct inhibition of I_f current by clonidine, however slight, could

enhance the overall benefits from a reduction in heart rate and prove advantageous to the patient suffering the effects from sympathetic overstimulation. It is also conceivable that HCN channels ubiquitously expressed in the nervous system may be similarly inhibited by clonidine, and this might partially mediate some of the neuronal effects of clonidine previously attributed to α_2 -receptors (Kroin et al., 2004). While its poor selectivity for HCN channels will exclude its use solely for this purpose, clonidine may provide a lead structure for the development of novel HCN inhibitors, not only in the treatment of tachycardia, but perhaps also to target neuronal disorders in which HCN channels are involved.

Fig. 42: Clonidine lowers heart rate in wild-type mice via two distinct mechanisms. At doses sufficient to significantly lower blood pressure in wild-type mice (10 $\mu\text{g}/\text{kg}$), clonidine significantly decreased heart rate in both wild-type and α_{2ABC} -KO mice (figure 32). This finding demonstrates that clonidine elicits its bradycardic effect in mice not only via activation of α_2 -adrenergic receptors, but also via an α_2 -independent mechanism. Experiments with the spontaneously beating isolated right atria from α_{2ABC} -KO mice localized this

effect, and, with recombinant HCN channel subtypes as well as with SAN cells isolated from α_{2ABC} -KO mice, clonidine was shown to inhibit the I_f pacemaker current.

VIII. Attachments

8.1. List of abbreviations

α_{2A} D79N-mutant	transgenic mouse line expressing an α_{2A} -adrenergic receptor with a D α N point mutation at position 79
AA	arachidonic acid
AC	adenylyl cyclase
ADHD	attention deficit hyperactivity disorder
ADP	adenosine diphosphate
ANOVA	analysis of variance
APD50	50% of action potential duration
APD90	90% of action potential duration
ATP	adenosine triphosphate
AV	atrioventricular
BaCl	barium chloride
α ARK	α -adrenergic receptor kinase
B_{max}	total number of binding sites
bp	base pairs
BSA	bovine serum albumin
$^{\circ}$ C	degrees centigrade
CaCl ₂	calcium chloride
cAMP	cyclic adenosine monophosphate
cDNA	complementary DNA (deoxyribonucleic acid)
CHO	cell line derived from Chinese hamster ovary tissue
CL	cycle length
CNS	central nervous system
CO ₂	carbon dioxide
COMT	catechol-O-methyltransferase
COX	cyclooxygenase
cpm	counts per minute
DD	diastolic depolarization
DHBA	3,4-dihydroxy benzylamine hydrobromide
DMEM	Dulbecco's modified Eagle's medium
DNA	deoxyribonucleic acid

dNTP	deoxyribonucleoside triphosphate
ECG	electrocardiogram
EDTA	ethylenediamine tetraacetic acid
EGF	epidermal growth factor
ERK	extracellular signal regulated kinase
ES cells	embryonic stem cell line
FRET	fluorescence resonance energy transfer
G418	geneticin; a selection agent in transfection
GAP	GTPase activating protein
GDP	guanosine diphosphate
GEF	guanine nucleotide exchange factor
GIRK channel	G protein-activated inward rectifier K ⁺ channel
GPCR	G protein coupled receptor
GTP	guanosine triphosphate
HB-EGF	heparin-binding EGF-like growth factor
HClO ₄	perchloric acid
HCN	hyperpolarization activated, cyclic nucleotide-gated cation
HE	hematoxylin and eosin (HE)
HEK293	human embryonic kidney cell line
HeLa	Henrietta Lacks, donor of cervix carcinom cells
HEPES	N-(2-hydroxyethyl)piperazine-N'-2-ethanesulfonic acid
HPLC	high performance liquid chromatography
IC ₅₀	inhibitory concentration 50
I _f	pacemaker current ("funny" current)
ip	intraperitoneal
IRAS-1	imidazoline receptor antisera-selected type 1 cDNA
iv	intravenous
JNK	c-jun N-terminus kinase (synonymous with SAPK)
K ⁺ _{ATP} channel	ATP-sensitive K ⁺ channel
KCl	potassium chloride
K _d	dissociation equilibrium constant
KH ₂ PO ₄	potassium dihydrogen phosphate
KO	knockout
KOH	potassium hydroxide

L2	second lumbar vertebra
L-DOPA	3,4-dihydroxy-L-phenylalanine
LOX	lipoxygenase
LV	left ventricular
M effect	mesomeric effect
MAO	monoamine oxidase
MAPK	mitogen-activated protein kinase
MDCKII	Madin-Darby canine kidney II cell line
MEK	mitogen-activated protein kinase kinase (MAP2K; MKK)
MgCl ₂	magnesium chloride
MgSO ₄ x 7H ₂ O	magnesium sulfate (heptahydrate)
MKKK	mitogen-activated protein kinase kinase kinase (MAP3K)
MMP	membrane metalloproteinase
mRNA	messenger RNA (ribonucleic acid)
Na(CH ₃ COO)	sodium acetate
NaCl	sodium chloride
NaHCO ₃	sodium bicarbonate
NaH ₂ PO ₄	sodium dihydrogen phosphate
NaOH	sodium hydroxide
Na ₂ SO ₃	sodium sulfite
NH ₄ Cl	ammonium chloride
NO	nitric oxide
NRL	nucleus reticularis lateralis
NTS	nucleus tractus solitarius
OS	overshoot
PBS	phosphate buffered saline
PC-12	rat pheochromocytoma cell line
PCR	polymerase chain reaction
PEI	polyethylenimine
PKC	protein kinase C
PLC	phospholipase C
PLA2	phospholipase A2
PNMT	phenylethanolamine N-methyl transferase
PNS	peripheral nervous system
RGS	regulator of G protein signaling

RP	resting potential
RP-18	reversed phase chromatographic column (non-polar)
rpm	rotations per minute
RVLM	rostral ventrolateral medulla
S1P ₁	sphingosine-1-phosphate receptor
SAN	sino-atrial node
SAPK	stress-activated protein kinase (synonymous with JNK)
SH domain	Src homology domain; binds phosphotyrosine residues
T1	first thoracic vertebra
TAE	Tris-acetate-EDTA
T _m	hybridization temperature of primer
TXA ₂	thromboxane
V _{0.5}	half-maximum activation voltage
WT	wild-type

8.2. Acknowledgements

I would like to thank my advisor, Prof. Dr. Lutz Hein, for his outstanding comments, critique and suggestions throughout the preparation and completion of my dissertation. I am grateful for having had the opportunity to work in a group of such high scientific standards.

Dr. Xiangang Zong and Prof. Dr. Martin Biel at the Ludwig-Maximilians-Universität in Munich contributed their long-standing expertise in HCN channels and provided us the means to demonstrate that clonidine indeed inhibits HCN channels, and also the mechanism by which it does so.

Both Marianne Babl and Reinhard Wölfel from the Institut für Pharmakologie und Toxikologie in Würzburg played instrumental roles in the preparation of and measuring of catecholamine samples, respectively.

Roland Jahns kindly performed the echocardiographic measurements of the mice.

Above all, I would like to thank my family for their encouragement, patience and understanding during preparation of my dissertation. Without their support this work would very likely not have come to fruition.

8.3. Past publications and lectures

publications

46th Spring Meeting of the Deutsche Gesellschaft für experimentelle und klinische Pharmakologie und Toxikologie, April 15-17, 2005 Mainz, Germany: Knaus A and Hein L (2005) Clonidine exhibits bradycardic and hypoglycemic effects in mice lacking all three alpha(2)-adrenergic receptor subtypes. *Naunyn-Schmiedebergs Arch Pharmacol* **371**:R26-R26 106 Suppl. 1 Feb 2005.

45th Spring Meeting of the Deutsche Gesellschaft für experimentelle und klinische Pharmakologie und Toxikologie, March 9-11, 2004 Mainz, Germany: Knaus A and Hein L (2004) alpha(2)-adrenergic receptor subtypes: All three control the sympathetic system. *Naunyn-Schmiedebergs Arch Pharmacol* **369**:R24-R24 93 Suppl. 1 Mar 2004.

8.4. Curriculum vitae

Anne Elizabeth Knaus
Fichtenstr. 23
97199 Ochsenfurt
09331-20871
thorald@aol.com

Education: One year internship, 2000-2001, completed with 3rd State Exams

Universität Würzburg, 1996-2000
School of Pharmacy completed with 2nd State Exams, (grade point average 1.5)

Western Michigan University, 1991-1996
Bachelor of Arts, summa cum laude

Certification: Licensed pharmacist (Germany) since 2002

Radiopharmacy, postgraduate diploma, according to the guidelines of the European Association of Nuclear Medicine, completed 2004

Training as Radiation protection officer, completed 2003

Experience: Pharmacist, Stadt Apotheke Ochsenfurt
Nov. 2006-current

Research assistant / doctoral student, Department of Pharmacology, Universität Würzburg, March 2003-Nov. 2006

Pharmacist, Engel Apotheke Ochsenfurt
Jan. 2002-March 2003

Pharmacist, Schloß-Apotheke Würzburg-
Rottenbauer
Jan. 2002-March 2003

Internship spring 2001-fall 2001
Kneipp Werke, Hohestadt,
Analytical Department
Objective: development of a new
quantitative assay of *Plantago lanceolata*
preparations for pharmacopeia

Internship fall 2000-spring 2001
Stadt Apotheke Ochsenfurt
