

Implications of self-targeting by type I CRISPR-Cas systems

Auswirkungen des Selbst-targetings durch Typ I CRISPR-Cas Systeme

Doctoral thesis for a doctoral degree
at the Graduate School of Life Sciences,
Julius-Maximilians-Universität Würzburg,
Section Infection and Immunity

submitted by

Franziska Wimmer

from

Traunstein

Würzburg, 2022

Submitted on:

Members of the Thesis Committee

Chairperson: Prof. Dr. Manfred Gessler

Primary Supervisor: Prof. Dr. Chase Beisel

Supervisor (Second): Prof. Dr. Cynthia Sharma

Supervisor (Third): Jun. Prof. Dr. Neva Caliskan

Supervisor (Fourth): Prof. Dr. Frederik Börnke

Date of Public Defence:

Date of Receipt of Certificates:

The presented work has been carried out as a member of the Graduate School of Life Science under the supervision of Prof. Dr. Chase L. Beisel at the Helmholtz Institute for RNA-based Infection Research (HIRI) in Würzburg between April 2018 and April 2022.

Summary

CRISPR-Cas systems are highly diverse and canonically function as prokaryotic adaptive immune systems. The canonical resistance mechanism relies on spacers that are complementary to the invaders' nucleic acids. By accidental incorporation or other mechanisms, prokaryotes can also acquire self-targeting spacers that are complementary to their own genome. As self-targeting commonly leads to lethal autoimmunity, the existence of self-targeting spacers poses a paradox. In Chapter 1, we provide an overview of the prevalence of self-targeting spacers, summarize how they can be incorporated, and which means can be employed by the host to evade lethal self-targeting. In addition, we outline alternative functions of CRISPR-Cas systems that are associated with self-targeting spacers. Whether CRISPR-Cas systems can efficiently target their own genome depends heavily on the presence of protospacer adjacent motifs (PAMs) next to the target region. In Chapter 2, we developed a method to determine PAM requirements. Thereby, we specifically focused on type I systems that engage multi-protein complexes, which are challenging to assess. Using the cell-free transcription-translation (TXTL) system, we developed an enrichment-based binding assay and validated its reliability by examining the well-known PAM requirements of the *E. coli* type I-E system. In Chapter 3, we applied the TXTL-based PAM assay to assess 16 additional CRISPR-Cas systems. These 16 systems included three CRISPR-Cas associated transposons (CASTs). CASTs are recently discovered transposons that employ CRISPR-Cas systems in a non-canonical function for the directed integration of the transposon. To further characterize CASTs in TXTL outside their PAM requirements, we reconstituted the transposition of CASTs in TXTL. In Chapter 4, we turned to non-canonical self-targeting CRISPR-Cas systems, which were already discussed in Chapter 1. While investigating how the plant pathogen *Xanthomonas albilineans* survives self-targeting by its two endogenous CRISPR-Cas systems, we identified multiple putative anti-CRISPR proteins (Acrs) in the genome of *X. albilineans*. Two of the Acrs, named AcrIC11 and AcrIF12_{Xal}, inhibited degradation by their respective CRISPR-Cas systems but still retained Cascade-binding ability, and appear responsible for the lack of autoimmunity in *X. albilineans*. In summary, we developed new technologies that eased the investigation of non-canonical multi-component systems and, if applied to additional systems, might reveal unique properties that could be implemented in new CRISPR-Cas based tools.

Zusammenfassung

CRISPR-Cas-Systeme sind sehr vielfältig und funktionieren kanonisch als prokaryotische adaptive Immunsysteme. Der kanonische Resistenzmechanismus basiert auf Spacern, die komplementär zu den Nukleinsäuren der Eindringlinge sind. Durch zufällige Inkorporation oder andere Mechanismen können Prokaryoten auch Spacer integrieren, die komplementär zu ihrem eigenen Genom sind. Da Selbst-targeting in der Regel zu letaler Autoimmunität führt, stellt die Existenz von selbst-targeting Spacern ein Paradoxon dar. In Kapitel 1 geben wir einen Überblick über die Verbreitung von selbst-targeting Spacern, fassen zusammen, wie sie eingebaut werden können und welche Mittel der Wirt einsetzen kann, um sich dem letalen Selbst-targeting zu entziehen. Darüber hinaus werden alternative Funktionen von CRISPR-Cas-Systemen skizziert, die mit selbst-targeting Spacern in Verbindung gebracht werden. Ob CRISPR-Cas-Systeme Ziele in ihrem eigenen Genom erkennen können, hängt stark davon ab ob bestimmte Motive neben der Zielregion (protospacer adjacent motifs, PAMs) vorhanden sind. In Kapitel 2 haben wir eine Methode entwickelt, um die Anforderungen an PAMs zu bestimmen. Dabei konzentrierten wir uns speziell auf Typ I Systeme, deren Erforschung durch Nutzung von Multiproteinkomplexen erschwert wird. Unter Verwendung des zellfreien Transkriptions-Translations-Systems (TXTL) entwickelten wir einen Test der zur Anreicherung erkannter PAMs führt. Seine Zuverlässigkeit validierten wir, indem wir die bekannten PAM-Anforderungen des *E. coli* Typ I-E Systems untersuchten. In Kapitel 3 wendeten wir den TXTL-basierten PAM-Assay an, um 16 weitere CRISPR-Cas-Systeme zu untersuchen. Zu diesen 16 Systemen gehörten drei CRISPR-Cas-assoziierte Transposons (CASTs). CASTs sind kürzlich entdeckte Transposons, die CRISPR-Cas-Systeme in einer nicht-kanonischen Funktion für die gerichtete Integration des Transposons einsetzen. Um CASTs in TXTL außerhalb ihrer PAM-Anforderungen weiter zu charakterisieren, haben wir die Transposition von CASTs in TXTL rekonstruiert. In Kapitel 4 wandten wir uns den nicht-kanonischen, selbst-targeting CRISPR-Cas-Systemen zu, die bereits in Kapitel 1 behandelt wurden. Während wir untersuchten, wie das Pflanzenpathogen *Xanthomonas albilineans* Selbst-targeting durch seine beiden endogenen CRISPR-Cas-Systeme überlebt, identifizierten wir mehrere mutmaßliche Anti-CRISPR-Proteine (Acrs) im Genom von *X. albilineans*. Zwei dieser Acrs, AcrIC11 und AcrIF12_{Xal}, hemmten die Degradation durch ihre jeweiligen CRISPR-Cas-Systeme, erlaubten aber dennoch DNA-Bindung durch Cascade. Diese beiden Acrs scheinen für das Fehlen von Autoimmunität bei *X. albilineans* verantwortlich zu sein. Zusammenfassend lässt sich sagen, dass wir neue Technologien entwickelt haben, die die Untersuchung von nicht-kanonischen Mehrkomponentensystemen erleichtert haben und bei Anwendung auf weitere Systeme einzigartige Eigenschaften offenbaren könnten, die in neue CRISPR-Cas-basierte Tools implementiert werden könnten.

Introduction

Bacterial immune systems

Nature is a dynamic environment, and its members are prone to a never-ending evolutionary process. In this rough world everything tries to survive, often at the costs of others. This battle of survival can be described with the “Red Queen Hypothesis” (1). A constant pressure exists that triggers continuous development of ways to escape lethal attack by a hostile organism. This ongoing arms race can once again be found between bacteria and bacteriophages (hereafter called phages) (2). Thereby, bacteria invented various strategies to defend from invading phages.

As an early step within bacterial defense, phage entry can be blocked by surface modifications (3, 4). If a phage still manages to enter the bacterial cell and successfully injects its genome, additional measures come into play that cleave foreign nucleic acids or block phage replication. One example are restriction-modification (R-M) systems that are present in 74% of prokaryotes (5) and cleave phage DNA. R-M systems function by recognizing specific sequence motifs in phages followed by endonucleolytic DNA cleavage (6). Another example of an immune system responsible for bacterial defense upon phage entry is the chemical defense (7). Bacteria produce small molecules that can stop phage replication, which is often achieved by the DNA-intercalating properties of these secondary metabolites.

As a late step in bacterial immunity, abortive infection (Abi) systems are activated if the first lines of defense fail. The infected bacterium commits suicide or enters growth arrest to prevent phage replication. These altruistic defense mechanisms prevent phage spread and protect other members in the bacterial community from phage infection (8). One example of such an Abi system is the lambda T4rII exclusion (Rex) system (9–11). Once the system is activated, an ion channel in the bacterial membrane is formed, leading to membrane depolarization and reduced ATP levels (10, 11). Consequently, cell growth is inhibited, and phage infection is stopped. A second example of an Abi system is the recently discovered cyclic oligonucleotide-based anti-phage signaling system (CBASS). Upon phage infection, CBASS produces cyclic oligonucleotides that activate the diverse effector proteins (12). Cell death can be caused via non-specific DNA degradation, membrane disruption by phospholipases or ion channel formation, and other to-date unknown mechanisms (12–14). This list of bacterial defense systems is by far incomplete. Bacteria constantly having to defend from attacking phages forced them to evolve a huge diversity of defense systems that is still not fully explored.

CRISPR-Cas systems

Important members of bacterial immune systems that were not mentioned yet are CRISPR-Cas (Clustered Regularly Interspaced Short Palindromic Repeats - CRISPR-associated) systems. These systems are the only adaptive immune systems of bacteria and archaea and are present in about 40% of all bacteria and 85% of all archaea (15). Generally, CRISPR-Cas systems confer immunity in three steps (**Figure 1**). As a first step (acquisition), parts of the invaders' nucleic acids are acquired as spacers in CRISPR arrays separated by repeats (16). These spacers act as memories of past infections. To integrate spacers, Cas1 and Cas2 are required (17, 18) and they can be assisted by accessory factors or effector proteins (19). In the second step of CRISPR-Cas immunity (biogenesis), the CRISPR arrays are transcribed as long precursor CRISPR-RNA (crRNA) and processed in mature crRNAs. Processing is achieved by various Cas proteins whereby RNase III can also be employed (20). During the last step (interference), the crRNA forms a ribonucleoprotein (RNP) complex with the effector protein or the effector protein complex and, upon reinfection, guides the CRISPR-Cas machinery to the invader (21). Foreign nucleic acids are recognized by their complementarity to the spacer portion of the crRNA and are often differentiated from host nucleic acids by protospacer adjacent motifs (PAMs) that are located 5' or 3' of the target region (22, 23). A lack of complementarity to the repeat portion within the host can also be used to differentiate between foreigner and host (24, 25). Subsequent DNA or RNA cleavage leads to clearance of the intruder.

Figure 1: CRISPR-Cas systems act in the steps. The *E. coli* type I-E system is exemplified here.

Although this mode of action for CRISPR-Cas immunity generally follows the same principle for all CRISPR-Cas systems, CRISPR-Cas systems are highly diverse. To-date, there are two classes, six types and more than 30 subtypes uncovered (15) (**Figure 2**). High variability can be found in the interference steps, where class I systems (types I, III and IV) utilize multi-protein complexes and class II systems (types II, V and VI) rely on a single multi-domain protein (**Figure 2**) (15). The mode of action differs not only between the two classes but also between the six types.

Figure 2: High diversity of CRISPR-Cas systems. The two classes of CRISPR-Cas systems are depicted consisting of six different types. The modes of action for the different CRISPR-Cas types are shown in a simplified version.

Class 1 systems contain the most abundant CRISPR-Cas system in nature - type I - representing about 50% of all CRISPR-Cas systems (15, 26). Type I systems canonically bind dsDNA by Cascade (CRISPR-associated complex for antiviral defense) that consist of multiple Cas proteins bound to a mature crRNA (27) (**Figures 1 and 2**). Upon recognition and binding of a DNA target, Cascade recruits the nuclease Cas3 (28), which leads to DNA degradation (29). Type III systems recognize RNA (30, 31) (**Figure 2**). Target RNA lacking complementarity with the repeat portion of the crRNA is bound by an RNP complex including Cas10-Csm or Cas10-Cmr protein complexes (24, 32). Subsequently, sequence-specific RNase activity and ssDNase activity is stimulated (32). Furthermore, cyclic oligoadenylates are produced by Cas10 that activate non-specific RNA cleavage by accessory proteins (33–35). The least studied CRISPR-Cas system is type IV, which is the last member of class 1 systems. The RNP complex in type IV systems is formed by Csf proteins and the crRNA and can lead to plasmid clearance (36). Type IV-A systems utilize the endonuclease DinG for their activity, while other subtypes lack this accessory protein (15, 36). Nevertheless, the exact mechanism of action for type IV systems is still not fully understood.

Class 2 systems contain the most studied CRISPR-Cas type - type II. Type II systems rely on Cas9 for interference activity but also require *trans*-activating crRNA (tracrRNA) to target dsDNA (37) (**Figure 2**). Binding of Cas9 to a target region next to a PAM sequence activates DNA cleavage activity of the effector protein (37). Type V systems only rely on tracrRNA or scoutRNA (short-complementarity untranslated RNA) in some subtypes (38, 39). Generally, Cas12 is guided to its dsDNA target by the mature crRNA followed by cleaved of the double-stranded target DNA (40) and non-specific ssDNA cleavage (41). Type VI systems represent the last member of class 2 CRISPR-Cas systems and are the only members of both classes systems that exclusively target RNA. Recognition of a target RNA sometimes requires a PFS (protospacer flanking site) or lack of extended complementarity between crRNA and target RNA (25, 42). Cas13, the effector protein of type VI binds its RNA target and subsequent RNA-cleavage activity gets activated. Thereby target-specific RNA but also non-specific RNA-cleavage can occur (42–45).

Mostly, CRISPR-Cas systems ensure the survival of their host by destruction of foreign nucleic acids that clears the intruder (37, 46). However, as some systems have the ability to non-specifically cleave DNA and/or RNA, these systems can also cleave or degrade host DNA/RNA (35, 43, 47, 48). Such collateral activity results in cell death or dormancy and turns the CRISPR-Cas system into an Abi system.

Anti-CRISPR proteins can counteract CRISPR-Cas immunity

As phages and bacteria constantly evolve in the battle for survival, phages also developed diverse mechanisms to circumvent bacterial attacks (49, 50). Here, we concentrate on phage mechanisms to escape from targeting by CRISPR-Cas systems. One means to escape from attack by CRISPR-Cas systems are mutations within the phage genome. Thereby mutating the spacer-complementary region or the adjacent PAM can avert CRISPR-Cas induced targeting (51). However, mutations in the phage genome might come with a fitness cost as expression of important genes could be impaired. Anti-CRISPR proteins (Acrs) represent a method to inactivate CRISPR-Cas systems without the need for genome mutations.

To-date, Acrs inhibiting all types of CRISPR-Cas systems besides type IV are known, although not for all subtypes (52–64). Acrs inhibiting type I-G CRISPR-Cas systems are still missing and only one inhibiting protein each is found for the type I-A, I-B and I-D systems (52, 53, 55). The amount of type II Acrs differs a lot between subtypes, with many Acrs discovered against type II-A, none for type II-B and few for type II-C (58, 59, 65–76). Only two type III Acrs are known so far (60, 61), although AcrIII-1 might be active against multiple type III systems as it leads to degradation of the signaling molecule cA_4 that plays an important role in many type III Acrs (60). For type V systems solely Acrs inhibiting type V-A (54, 62) were discovered. Finally, in type VI systems few Acrs were discovered inhibiting type VI-A and -B, although many of them are under debate (53, 63, 64, 77). Nevertheless, this list will most likely change in the near future as the search for new Acrs is still ongoing.

As these various Acrs inhibit a diverse set of CRISPR-Cas systems, the mode of action of these proteins is also highly variable. The identified mechanisms can be grouped in four general categories (78) with AcrIII-1 being the single member of one group. The remaining three groups are: prevention of CRISPR-Cas complex assembly, inhibition of effector binding, and suppression of effector cleavage. Mostly, Acrs achieve the former named outcomes by direct interaction with Cas proteins and only few Acrs were identified so far that use enzymatic strategies to achieve their goal (60, 73, 79–81). Nevertheless, the mechanism of action of many Acrs is still unknown.

The search for new Acrs could therefore not only discover enzymes inhibiting additional subtypes but also expand the already known mechanistic set used by Acrs. The first Acrs were identified in 2013 as type I-F counterplayers in *Pseudomonas* spp phages (57) followed by Acrs against the type I-E system discovered in the same phage group (56). But as most Acrs do not share sequence similarity, the search for additional Acrs was challenging. A putative transcriptional regulator containing a helix-turn-helix motif that was found to be encoded immediately upstream of the few identified Acrs eased the search for new Acrs (57). A “guilt-

by-association” method was employed to search for these helix-turn-helix containing proteins, termed anti-CRISPR associated (Aca) proteins, and novel Acrs were discovered encoded adjacent to *aca* genes (54, 59, 76, 82). To-date, 13 different Aca proteins are known (54, 57, 59, 75, 82–85) and their function as regulators controlling Acr expression was assigned (86–88).

Identification of new Acrs did not solely rely on Aca proteins and other means were established that for instance utilized phage infections or self-targeting spacers. In the first example, bacteria are infected by various phages and the efficiency of the bacterial encoded CRISPR-Cas system in defending phage infection was assessed (55, 65, 66). Potential Acr-bearing phages can be identified by successful bacterial infection. The individual genes encoded in the phage genome can then be tested separately for their function in blocking CRISPR-Cas immunity. The last example mentioned here interrogates bacteria that encode spacers with complementarity to their own genome. As cleavage of the bacterial genome is expected to lead to autoimmunity, the presence of self-targeting CRISPR-Cas systems can indicate the existence of Acrs that protect the bacterium from lethal self-targeting (58, 62). By using these and other methods (89), the discovery of new Acrs is just a matter of time.

Self-targeting CRISPR-Cas systems can harbor alternative functions

Self-targeting CRISPR-Cas systems are not always a burden to their host as they can unleash non-canonical functions of CRISPR-Cas systems (90, 91). One example is the primarily DNA-binding type I-F CRISPR-Cas system of *Pseudomonas aeruginosa*. Using a partial complementary crRNA, the bacterium converts the type I-F system into an RNA-targeting system that leads to degradation of *lasR* mRNA (92). As a result, *P. aeruginosa* faces a decreased immune reaction during host invasion (**Figure 3**). The same CRISPR-Cas system also harbors a second alternative function that is not necessarily beneficial for the bacterium. A partially complementary region in the genome of *P. aeruginosa* is targeted by the type I-F system, leading to nicking by Cas3 and induction of the SOS pathway. As a consequence, swarming motility is impaired and cell death of biofilm forming cells while sparing planktonic cells is induced (93–95) (**Figure 3**). Other CRISPR-Cas systems use self-targeting spacers for gene regulation (96–98). *Francisella novicida* utilizes Cas9 and scaRNAs (small CRISPR/Cas-associated RNAs) to regulate virulence-attenuating genes (96). A type I-B system becomes “addictive” by silencing the toxin CreT with the CRISPR RNA-resembling antitoxin (CreA) RNA that guides Cascade to a partial complementarity target in the *creT* promoter region (98) (**Figure 3**). These examples exemplify that self-targeting spacers can be beneficial to the host in various ways.

Figure 3: Self-targeting CRISPR-Cas systems can lead to several outcomes. Self-targeting CRISPR-Cas systems can lead to cell death by autoimmunity (upper left) or reduced recognition by the host immune system during bacterial infection (upper right). Self-targeting was also shown to induce cell death of biofilm forming cells while sparing planktonic cells (lower left). Finally, a CRISPR-Cas system can become addictive to its host by Cascade-induced gene regulation preventing toxin production (lower right).

Also, mobile genetic elements can use crRNAs complementary to the bacteria's genome for their own purpose. Prominent examples that were recently discovered are CRISPR-Cas associated transposons (CASTs) (99–106). The Tn7-like transposons utilize CRISPR-Cas systems for RNA-guided transposition (103, 104). CASTs miss the mobilization gene *tnsE* and often *tnsD* required for transformation (101, 106). Instead, they harbor a CRISPR-Cas system lacking an acquisition module and a nuclease. A crRNA complementary to a bacterial genome or a mobile genetic element can guide insertion of the CAST within a region downstream of the target site (103, 104). So far, type I-F, type I-B and type V-K CRISPR-Cas systems are

shown to cooperate with Tn7-like transposons (102–104). A bioinformatic search for additional CASTs also identified type I-C and type IV systems associated with Tn7-like transposons and non-Tn7-CASTs associated with type I-E or inactivated type V systems, yet their functionality still needs to be explored (100). In summary, self-targeting CRISPR-Cas systems can be used by bacteria or mobile genetic elements to execute functions beyond adaptive immunity.

Applications of type I CRISPR-Cas systems

CRISPR-Cas systems are not only known for their biological functions but are also widely utilized as biotechnological tools. Class 2 systems are intensively used in CRISPR-Cas based applications. The preference of class 2 systems is mostly due to them utilizing one single protein for all functions and not consisting of a multi-protein complex like class 1 systems (15). Cas9 is the most established CRISPR-Cas system for biotechnological tools, nevertheless, Cas12 is now also heavily utilized and Cas13 gains more attention due to its RNA-targeting properties (107). Applications of class 2 CRISPR-Cas systems range from genome engineering in bacteria (108) over diagnostic tools (109) to even disease treatment in clinical trials (110).

Nevertheless, technologies involving class 1 systems, mostly focusing on type I, are emerging (111). As type I systems are the most common CRISPR-Cas system in nature (15, 26), harnessing type I systems within their natural host seems attractive. Especially as exogenous expression of Cas9 or Cas12a can lead to cytotoxicity and difficulties during plasmid delivery can be faced (112, 113). By utilizing the endogenous type I CRISPR-Cas systems, there is no need to transform a plasmid encoding for the effector. Solely a minimal CRISPR array targeting the genomic location selected for editing and a repair template for homology directed repair that includes the desired edits has to be transformed (114) (**Figure 4A**). If an endogenous system efficiently targets its own genome without a repair template, bacteria are usually prone to cell death (115). Therefore, lethal chromosomal targeting can be utilized to reprogram endogenous CRISPR-Cas systems into specific antimicrobials (116, 117) (**Figure 4B**). Furthermore, by mutation or deletion of the nuclease Cas3, endogenous type I CRISPR-Cas systems can be turned into gene regulators (118–120) (**Figure 4A**).

Unique properties of type I systems further promote their use in biotechnology. For instance, genome-editing with type I systems is less prone to off-target effects than type II systems. This is partly due to Cascade scanning DNA for complementary targets before recruitment of the nuclease Cas3. Thereby, an additional surveillance level is introduced upstream of nuclease cleavage that is not present in type II systems (121). Furthermore, Cas3 possesses the unique function of generating long range deletions in bacteria and in human cells that are challenging with Cas9 (121–124) (**Figure 4C**). Additionally, the multi-protein

nature of type I CRISPR effectors bears unique possibilities. As different tasks during CRISPR-Cas immunity are performed by separate proteins (e.g. nuclease: Cas3 (29), crRNA processing: Cas5 or Cas6 (125–127), PAM recognition: Cas8 (128, 129), backbone of Cascade: Cas7 (130)), Cas proteins can be used individually or easily left out to achieve diverse functions. One example is Cas3, as its removal turns type I systems, as mentioned previously, into gene regulators (118–120). A second example is Cas6. The RNA-binding properties of the small Cas6 protein can be reprogrammed to function in a highly sensitive and specific RNA-tracking platform (131). A third example utilizes the fact that Cascade complexes are assembled with a defined stoichiometry (Cas8₁-Cse2₂-Cas7₆-Cas5₁-Cas6₁ for *E. coli* type I-E Cascade) (27) (**Figure 1**). Thereby, each Cas7 interacts with 6 nts of the spacer and each Cse2 interacts with two Cas7 (128). By extending the spacer length by 6 nts or 12 nts, an additional Cas7 or two Cas7 and one Cse2, respectively, are included in Cascade formation (132). The enlarged Cascade can enhance gene silencing at some targets, potentially enabling fine-tuning of Cascade-binding. Summarizing, even though type I systems are not extensively used as biotechnological tools yet, some unique properties are already utilized. Nonetheless, due to the high diversity in type I CRISPR-Cas systems and their high prevalence in prokaryotes, additional functions likely await their discovery and use in new technologies.

Figure 4: Type I CRISPR-Cas systems utilized as technological tools. (A) Endogenous type I systems can be used to perform changes in the genome or to regulate gene expression. (B) Type I systems can also be turned into tailored antimicrobials where they kill specific bacteria while sparing others. (C) Cas3 has a unique function in introducing long range genomic deletions.

Overcoming challenges in studying type I CRISPR-Cas systems by the use of cell-free transcription-translation systems

To further uncover new functions and potential new applications of CRISPR-Cas systems, there is a need to advance investigations of type I systems to unravel the high diversity of these systems and their unique properties. Unfortunately, the fact that type I systems are utilizing multiple proteins to execute their functions did not only lead to unique biotechnological tools but also hampered the investigation and fundamental understanding of many type I systems. Four Cas proteins in type I-C systems are the minimal number of proteins that are involved in type I interference (15). Thereby, Cas8, Cas5, and Cas7 form the Cascade and Cas3 is recruited as the DNA-degrading nuclease (126, 133). Type I-E systems however consist of five Cas proteins forming Cascade and including the nuclease, six Cas proteins are required for efficient DNA degradation (27). If type I systems are studied *in vitro*, all required Cas proteins need to be overexpressed and extracted either separately or as an already formed Cascade complex additionally extracting Cas3 (21). Optimizing plasmid extraction can be time-consuming and expensive. Cell-based experiments encompass different challenges. First of all, expression of unknown proteins can be toxic (105). Secondly, several Cas proteins need to be expressed at once. Therefore, multiple Cas proteins have to be encoded on one plasmid to minimize the total number of plasmids that need to be transformed. The cloning process for these huge plasmids can be demanding.

To overcome all of these challenges, cell-free systems come in handy. Transcription-translation (TXTL) systems contain an intact transcription and translation machinery, therefore, providing circular or linear DNA is sufficient for RNA and protein expression (134). For investigation of CRISPR-Cas systems, the TXTL system based on *E. coli* cell lysate was established (135). This system can be generated from *E. coli* strains with the desired genotype or can be purchased ready-to-use (136). It can also be handled in small volumes of a few microliters, which facilitates multiplexed experiments (137). As TXTL can be supplemented with polymerases like T7 RNA-polymerase that are not native to *E. coli*, genes can be cloned under promoters inactive within the cloning strain, circumventing potential protein toxicity (134). Furthermore, multiple plasmids can be added removing the need to minimize the number of plasmids used. So far, TXTL was mostly used to interrogate single effector CRISPR-Cas systems (62, 137–140), although it holds great potential to facilitate the future work in exploring the more complicated but very diverse multi-protein effector CRISPR-Cas systems and accelerate their use in technologies (105, 135).

In this work, TXTL was used in Chapter 2 and Chapter 3 to develop new techniques to overcome challenges in investigating type I CRISPR-Cas systems (105). These newly

established approaches were used to uncover properties of the recently discovered CASTs in Chapter 3 and study self-targeting CRISPR-Cas systems in Chapter 3 and Chapter 4. The results of this work lay the foundation for uncovering novel alternative functions of CRISPR-Cas systems that are reviewed in Chapter 1, and their use as new technologies.

Chapter 1: CRISPR-Cas systems and the paradox of self-targeting spacers

Author contributions:

FW and CB conceived and wrote the manuscript.

Abstract

CRISPR-Cas immune systems in bacteria and archaea record prior infections as spacers within each system's CRISPR arrays. Spacers are normally derived from invasive genetic material and direct the immune system to complementary targets as part of future infections. However, not all spacers appear to be derived from foreign genetic material and instead can originate from the host genome. Their presence poses a paradox, as self-targeting spacers would be expected to induce an autoimmune response and cell death. In this review, we discuss the known frequency of self-targeting spacers in natural CRISPR-Cas systems, how these spacers can be incorporated into CRISPR arrays, and how the host can evade lethal attack. We also discuss how self-targeting spacers can become the basis for alternative functions performed by CRISPR-Cas systems that extend beyond adaptive immunity. Overall, the acquisition of genome-targeting spacers poses a substantial risk but can aid in the host's evolution and potentially lead to or support new functionalities.

Introduction

CRISPR-Cas systems represent highly diverse adaptive immune systems found in many bacteria and most archaea (Barrangou et al., 2007; Sorek et al., 2013; Koonin et al., 2017). These systems consist of two general parts: Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) arrays and CRISPR-associated (Cas) proteins. CRISPR arrays represent the immunological memory of prior infections encoded within individual spacers separated by conserved repeats. Cas proteins carry out the adaptive immune

functions. The Cas proteins are highly diverse, resulting in CRISPR-Cas systems currently being grouped into two classes, six types, and over 30 subtypes (Makarova et al., 2015; Koonin et al., 2017; Koonin and Makarova, 2019).

While the specific proteins and biomolecular mechanisms vary, all systems act through three general steps as part of adaptive immunity. The first step, acquisition, incorporates pieces of invading nucleic acids, called protospacers, as new spacers within the CRISPR array. The protospacers are often selected based on the presence of a flanking protospacer adjacent motif (PAM) (Yosef et al., 2013; Wang et al., 2015). Acquisition requires the universal Cas proteins Cas1 and Cas2 (Yosef et al., 2012; Nuñez et al., 2014), although other accessory factors such as Cas4 (Kieper et al., 2018), Csa1 (Liu T. et al., 2017), Csn2 (Heler et al., 2015; Wei et al., 2015) and reverse transcriptase (RT) (Kojima and Kanehisa, 2008; Simon and Zimmerly, 2008; Silas et al., 2016) can also be involved. In type II CRISPR-Cas systems, the effector nuclease Cas9 can also play an essential role in the acquisition of new spacers (Heler et al., 2015; Wei et al., 2015). The acquired spacers serve as DNA records of prior infections that are passed to the host's progeny.

The second and third steps involve the biogenesis of CRISPR RNAs (crRNAs) from the CRISPR arrays followed by crRNA-directed immune defense. As part of crRNA biogenesis, the CRISPR array is, for most cases, transcribed into a long precursor CRISPR RNA (pre-crRNA) and processed into mature crRNAs by Cas proteins. In some cases, processing involves accessory factors such as RNase III (Carte et al., 2008; Deltcheva et al., 2011; Behler et al., 2018; Lee et al., 2018, 2019). The crRNA then forms a complex with Cas effector proteins to target foreign nucleic acids. Class 2 CRISPR-Cas systems rely on only one protein to bind and cleave their targets, with type II systems and some type V systems also requiring a *trans*-activating crRNA (tracrRNA) for effector complex formation (Deltcheva et al., 2011; Shmakov et al., 2015; Zetsche et al., 2015). Class I systems in contrast rely on multiple proteins that form a multi-subunit effector complex (Brouns et al., 2008; Hale et al., 2009). The resulting ribonucleoprotein complex then surveils the host's cytoplasm for DNA and/or RNA sequences that are complementary to the spacer and flanked either by a PAM or a sequence lacking complementarity to the corresponding portion of the crRNA repeat (Mojica et al., 2005; Marraffini and Sontheimer, 2010; Leenay and Beisel, 2017; Meeske and Marraffini, 2018).

One commonality across CRISPR-Cas systems is their reliance on the array-encoded spacers to direct CRISPR-based immunity. To-date, only 1–19% of identified spacers have been matched to potential protospacer sites, where most of the assigned spacers appear to be derived from the genome of bacteriophages (herein called phages), archaeal viruses (herein called viruses), plasmids or other organisms (Bolotin et al., 2005; Mojica et al., 2005; Pourcel et al., 2005; Marraffini and Sontheimer, 2008; Brodt et al., 2011; Bikard et al., 2012;

Shmakov et al., 2017). However, many of the assigned spacers match sequences within the host genome, what are generally called self-targeting spacers.

Figure 1: Acquisition of self-targeting spacers. (A) Overview of self-targeting by CRISPR-Cas systems. The CRISPR array is transcribed and processed into individual crRNAs that form a ribonucleoprotein complex with the Cas effector proteins (brown). One of the crRNAs encodes a self-targeting spacer (red) that directs binding to the complementary protospacer sequence (red) flanked by a PAM (orange) located on the genome, leading to autoimmunity and cell death. (B) Mobile genetic elements harboring a CRISPR-Cas target sequence can be incorporated into the host chromosome, leading to self-targeting. (C) Primed acquisition. The CRISPR effector complex recognizes a target, potentially generating cleaved products. These products can then be incorporated into the CRISPR array by the acquisition complex (blue), leading to acquisition of self-targeting spacers. (D) Spacer acquisition from RNA. RT-Cas1 forms a complex with Cas2 (white and blue) and leads to incorporation of self-targeting spacers derived from the host's RNA. (E) Virally driven acquisition of self-targeting spacers. The phage injects its genome into the host cell and the encoded *cas4* is expressed. In cooperation with the host's endogenous acquisition complex, the phage-derived Cas4 leads to the incorporation of genome-derived spacers into the host's CRISPR array.

Self-targeting spacers are unexpected due to an observed preference toward acquiring foreign genetic material (Levy et al., 2015) and heavy cytotoxicity to the host because self-targeting of the host's chromosome would lead to cell death (Stern et al., 2010; Jiang et al., 2013; Vercoe et al., 2013; Gomaa et al., 2014; **Figure 1A**). Here, we review the presence and consequences of self-targeting spacers. We address the known distribution of self-targeting spacers in sequenced CRISPR-Cas systems. We then discuss different mechanisms of acquisition that could generate self-targeting spacers and how these organisms can survive despite the potential for chromosomal targeting and autoimmunity. Finally, we report some of the beneficial functions that have been associated with the self-targeting spacers that can imbue CRISPR-Cas systems with functionalities that extend beyond adaptive immunity. This content greatly expands on an earlier mini-review on the consequences of chromosomal

targeting (Heussler and O'Toole, 2016) and incorporates recently reported examples of self-targeting reflecting alternative functions of these prevalent adaptive immune systems.

Natural occurrence of self-targeting spacers

Multiple studies have explored the source of spacers in diverse CRISPR-Cas systems, with recurring observations of self-targeting spacers. In the first broad study of matching protospacers, 88 of the analyzed 4,500 spacers were similar to known sequences, and 35% of these spacers matched chromosomal DNA not directly related to foreign genetic elements (Mojica et al., 2005). Separately, a study from 2008 found that 7% of spacers in different CRISPR-Cas systems from *Streptococcus thermophilus* matched chromosomal sequences (Horvath et al., 2008). One year later, the same group analyzed CRISPR-Cas systems from a more diverse set of lactic acid bacteria, reporting that 23 of the 104 spacers matched the chromosome (Horvath et al., 2009). Shortly thereafter, one study analyzed the CRISPR arrays of the 330 prokaryotes containing CRISPR-Cas systems included in the CRISPRdb database (Grissa et al., 2007) in 2010, with self-targeting spacers comprising 0.4% of all spacers (including the vast majority of spacers with no assignable protospacers) and appearing in 18% of the included prokaryotic genomes (Stern et al., 2010).

The number of sequenced organisms has increased over time, allowing more recent studies to more deeply and widely interrogate spacer origins. For instance, one study in 2017 screened 50,000 completely or partially assembled genomes, while another study in 2018 used the online tool CRISPRminer to evaluate more than 60,000 organisms harboring a CRISPR array (Shmakov et al., 2017; Zhang et al., 2018). Shmakov et al. assigned protospacer locations to 7% of the detected 363,460 unique spacers, with ~6% of these spacers matching prokaryotic genomes and 16% of these genome-matching spacers being potentially unrelated to (pro-)viral sequences (Shmakov et al., 2017). The study with CRISPRminer reported 22,110 self-targeting events in publications (Stern et al., 2010; Rauch et al., 2017; Watters et al., 2018) and could predict 6,260 additional putative self-targeting spacers in 4,136 organisms, implying that ~7% of the genomes within their database should harbor at least one self-targeting spacer (Zhang et al., 2018).

The natural acquisition of self-targeting spacers has also been observed as part of adaptive evolution studies between phages and their prokaryotic host. Two key studies relied on a strain of the bacterium *S. thermophilus* harboring two type II-A CRISPR-Cas systems (Paez-Espino et al., 2013, 2015). In these studies, only 0.01 – 0.04% of the observed new spacers matched the genome. These frequencies are lower than those reported in the large-scale bioinformatics studies, although this discrepancy can be attributed in part to the selective pressure exerted by the actively infecting phages.

Incorporation of self-targeting spacers

Given the frequency of self-targeting spacers and their potential for autoimmunity, we next discuss the circumstances under which a self-targeting spacer can be acquired. In particular, we consider five general scenarios that have been reported: naïve acquisition from DNA, protospacers within a transferred mobile genetic element (MGE), primed adaptation, naïve acquisition from RNA, and phage/virus-triggered acquisition from host DNA. For many of these scenarios, we address the extent to which acquisition differentiates between chromosomal and foreign genetic material and the known associated mechanisms. We finally must note that our understanding of CRISPR-based acquisition is still developing, and other mechanisms within the diversity of CRISPR-Cas systems likely await discovery.

Naïve acquisition

Naïve acquisition leads to the incorporation of new spacers without any influence from the existing pool of spacers. Cas1 and Cas2 are required while Cas4, Csn2 or Cas9 may be additionally needed depending on the system sub-type (Yosef et al., 2012; Nuñez et al., 2014; Heler et al., 2015; Wei et al., 2015; Kieper et al., 2018). It was known for many years that protospacers were commonly flanked by PAMs to allow targeting by the effector proteins to differentiate between self and non-self targets (Deveau et al., 2008; Horvath et al., 2008). However, it remained unclear how the acquisition machinery differentiated between invader and chromosomal DNA. In one of the first studies to systematically interrogate spacer acquisition, Levy and coworkers sequenced over 38 million newly acquired spacers following plasmid-based expression of Cas1 and Cas2 in an *Escherichia coli* strain harboring a CRISPR array but lacking endogenous *cas* genes. They found that spacers were preferentially acquired from replication forks, presumably due to stalling during replication and degradation by RecBCD. This preference resulted in 100-fold to 1,000-fold enrichment of spacers derived from a resident plasmid compared to the chromosome. The high-copy number plasmids present most of the replication forks in a replicating cell, partly explaining the preference toward high copy plasmids (Levy et al., 2015).

Another critical factor identified by Levy and coworkers was the presence of Chi sites. These sequence motifs interact with and prevent DNA degradation by RecBCD (Smith, 2012) at the sites of double-stranded DNA breaks that often occur at stalled replication forks (Kuzminov, 2001; Michel et al., 2001). Due to the fact that Chi sites occur approximately every 5 kb in the *E. coli* genome (El Karoui et al., 1999), these Chi sites were hypothesized to mark the host DNA as “self” and prevent acquisition of spacers from the host’s genome. The plasmids contained fewer Chi sites, likely further contributing to preferential acquisition from this DNA. Linear viral DNA would also offer a preferred substrate for RecBCD, resulting in DNA

fragments that can be used to generate new spacers (Levy et al., 2015). Phages are known to encode RecBCD inhibitors and some also encode a large number of Chi sites in their genome (Friedman and Hays, 1986; Murphy and Lewis, 1993; Bobay et al., 2013), thus potentially countering acquisition by CRISPR-Cas systems.

Liu et al. observed a different element influencing naïve acquisition in *Sulfolobus islandicus*, an archaeon that encodes one type I-A CRISPR-Cas system and two type III-B CRISPR-Cas systems. Following overexpression of *Csa3a* that drives expression of the type I-A acquisition genes, *S. islandicus* integrated spacers from the *csa3a* expression plasmid as well as from its own genome with a high bias toward the plasmid (Liu et al., 2015). Interestingly, for deletion mutants lacking RNA processing or nuclease activity, <28% of spacers were derived from the plasmid (Liu T. et al., 2017). While this fraction was far less than the >90% in a previous study (Liu et al., 2015), it still reflected preferential acquisition from plasmids when taking into account the relative length of the plasmid and chromosomal DNA (Liu T. et al., 2017). The stronger preference for plasmid DNA in the presence of an active CRISPR-Cas system may be explained in part by the cytotoxicity of genome targeting by the active but not impaired system upon self-targeting.

Spacer acquisition in type II CRISPR-Cas systems also appears to differ for active versus impaired CRISPR-Cas systems. Wei et al. (2015) looked at acquisition requirements in a type II-A CRISPR-Cas system by expressing the different CRISPR-Cas components on plasmids and monitoring spacer acquisition. They found that acquisition required the presence of Cas9, in contrast to spacer acquisition by Cas1 and Cas2 in type I CRISPR-Cas systems. Interestingly, the authors found that the cleavage activity of Cas9 contributed to an observed preference for acquisition from plasmid DNA. Specifically, by using a mutated Cas9 that disrupts its cleavage activity (dCas9), the authors shifted the fraction of plasmid-derived spacers from 68% to 4%, representing a loss of preference given the matching ratio of plasmid DNA to genomic DNA (Wei et al., 2015). In total, naïve acquisition by different types of CRISPR-Cas systems can lead to the incorporation of self-targeting spacers, although foreign genetic material is the predominant source of spacers. It would be interesting to investigate if the above reported phenomena can also be observed in different organisms or other CRISPR-Cas systems that rely on additional Cas proteins for acquiring new spacers.

Protospacer within transferred mobile genetic elements

Many self-targeting spacers identified in nature bear homology to MGEs such as transposons or prophages/proviruses that have been incorporated into the genome. These spacers could have been acquired prior to the incorporation of the MGE as a preventative measure, or afterward to induce cell death and prevent further spread of the MGE (**Figure 1B**). All evidence

of this mechanism comes from bioinformatic experiments. Looking at self-targeting spacers with 100% complementary to their predicted protospacer region, Stern et al. (2010) found an approximately equal distribution of protospacers from mobile elements encoded in the chromosome and non-mobile elements (47% vs. 53%). In comparison, Shmakov et al. (2017) assigned 83% of the self-targeting spacers to (pro-)phage sequences. The difference might arise from the greater abundance of sequenced MGEs over time (Geer et al., 2010; Akhter et al., 2012). Nevertheless, these frequencies leave ample spacers derived from non-mobile elements.

Primed adaptation

A different potential means of incorporating self-targeting spacers is through primed adaptation (or primed acquisition). Acquisition of spacers under primed adaptation requires target recognition with pre-existing spacers that are partially or fully complementary to the foreign DNA. Recognition leads to the acquisition of multiple spacers from sites in close proximity to the existing protospacer (Datsenko et al., 2012; Swarts et al., 2012; Richter et al., 2014; Jackson et al., 2019; **Figure 1C**).

Bioinformatic evidence indicates that primed adaptation is widespread in type I and type II CRISPR-Cas systems (Nicholson et al., 2019). Primed adaptation by type I systems involves degradation of the target site by Cas3 and incorporation of the degradation products as new spacers by Cas1 and Cas2 (Künne et al., 2016). Primed adaptation by type II systems is not well understood, although Nicholson et al. (2019) proposed two possible pathways: one that involves a main role of Cas9, and another involving host-specific processes such as DNA repair producing pre-spacers at the sites of target cleavage.

Regardless of the exact mechanism, primed adaptation is expected to preferentially incorporate foreign genetic material due to the pre-existence of more spacers derived from non-chromosomal elements. However, primed acquisition of host DNA could occur upon targeting MGE that were incorporated into a bacterial or archaeal genome (Nicholson et al., 2019). Primed acquisition outside of the borders of the MGE could also be triggered, leading to incorporation of non-mobile self DNA from the chromosome. Finally, spacers that evolved to target foreign DNA might prime with similar sequences in chromosomal DNA (Staals et al., 2016), where prior work showed that priming can occur even with 13 mutations in the target site relative to the pre-existing spacer (Fineran et al., 2014).

Naïve acquisition of RNA-derived spacers

One unique mode of acquisition is through relatively rare Cas proteins that recognize RNA rather than DNA. These proteins include a RT often translationally fused to Cas1 or to a fusion

between Cas1 and the Cas6 protein responsible for crRNA biogenesis. This unique RNA-acquiring machinery is predominantly associated with type III CRISPR-Cas systems but is also found with type I-E and type VI-A systems (Kojima and Kanehisa, 2008; Simon and Zimmerly, 2008; Toro and Nisa-Martínez, 2014; Silas et al., 2017; Toro et al., 2019a,b). For the few examples that have been studied, these RTs reverse-transcribe an acquired RNA into DNA to produce a substrate for acquisition (Silas et al., 2016). If the RNA-derived spacers are derived from host RNA, the associated type III CRISPR-Cas systems can now target the host and lead to autoimmunity (**Figure 1D**). Interestingly, self-targeting spacers have been found in three strains encoding a RT as part of their type III CRISPR-Cas systems (Silas et al., 2017; Zhang et al., 2018).

Other systems solely encode RT and Cas1 and lack all other Cas proteins, holding the potential to acquire self-targeting spacers without inducing autoimmunity. As one example, *Rivularia* sp. PCC 7116 encodes Cas1, Cas2, and RT in a distinct genomic island compared to the other CRISPR-Cas systems present in that bacterium. The CRISPR array associated with Cas1, Cas2 and RT harbors a spacer matching a hypothetical gene encoded on the bacterial chromosome (Silas et al., 2017; Kersey et al., 2018; Zhang et al., 2018). The lack of effector proteins suggests that these systems are used for alternative functions rather than immunity, although this has not been investigated to-date.

The unique sourcing of spacers from RNA raises questions about how the acquisition machinery selected some RNA sequences over others. Silas and coworkers sequenced the spacer content in an open-air culture of *Arthrospira platensis*, which encodes a RT-Cas1 fusion as part of its type III-B CRISPR-Cas system (Silas et al., 2017). Most of the associated protospacers could not be identified, and the few that could be identified traced to DNA viruses. Schmidt and coworkers were able to gain more extensive insights by monitoring spacer acquisition in *E. coli* following plasmid-based expression of the type III *Fusicatenibacter saccharivorans* RT-Cas1 and Cas2. While spacers were derived from RNAs encoded in the chromosome and plasmid, there was a strong preference for A/T-rich sequences at the ends of highly expressed genes. Interestingly, there was no obvious preference for a flanking motif or for plasmid-encoded RNAs (Schmidt et al., 2018). Further studies are needed to fully understand preferences exhibited by type III CRISPR-Cas systems for RNA acquisition.

Acquisition of self-targeting spacers triggered by foreign invaders

There is also evidence that phages can encode Cas proteins that drive endogenous CRISPR-Cas systems to preferentially acquire self-targeting spacers. The first direct evidence comes from studying the origin of spacers encoded within the CRISPR array of *Campylobacter jejuni* PT14 harboring a minimal type II-C CRISPR-Cas system (Hooton and Connerton, 2014). While

the spacers do not share 100% sequence identity with any known sequences, some of the spacers partially matched chromosomal sequences in the PT14 genome. Tracking spacer content in a co-culture of PT14 cells and CP8/CP30A phage revealed that all newly acquired spacers were derived from the host's chromosome and not the phage (Hooton and Connerton, 2014). The phage encoded a copy of the *cas4* gene involved in protospacer maturation as part of many CRISPR-Cas systems (Zhang et al., 2012; Lemak et al., 2013; Kieper et al., 2018; Lee et al., 2018), while the endogenous type II-C CRISPR-Cas system normally lacks this gene. The authors therefore attributed the unexpected self-targeting acquisition events to the phage encoded Cas4 (Hooton and Connerton, 2014; **Figure 1E**).

Further evidence that viral Cas4 can impact host acquisition was found in *S. islandicus*. Zhang and coworkers evaluated the impact of the viral *cas4* gene found in a *Sulfolobus* spindle-shaped virus by transforming a plasmid encoding the viral *cas4* into *S. islandicus*. Cells harboring the plasmid exhibited less frequent spacer acquisition, although the frequency of spacers acquired from the plasmid or chromosome did not change. Furthermore, overexpression of host Cas4 from a plasmid also led to reduced spacer acquisition. These findings suggest that overproduction of Cas4 can in some cases disable spacer acquisition. One explanation is that the viral encoded Cas4 serves as an anti-CRISPR protein (Acr) by preventing spacer acquisition and in turn enabling escape from CRISPR-Cas targeting (Zhang et al., 2019). While more work is needed to elucidate the underlying role of the virally encoded Cas4, these examples and the many other instances of virally encoded Cas4 (Krupovic et al., 2015; Hudaiberdiev et al., 2017) suggest the intriguing possibility that phages and viruses could be actively directing the acquisition of spacers.

Surviving self-targeting by CRISPR-Cas systems

Unrelated to how prokaryotes incorporate spacers that target their own genome, cells must overcome self-targeting by their own CRISPR-Cas system to survive. CRISPR-based interference against the host's own genome is expected to lead to lethal autoimmunity due to the nuclease cutting within or close to their target site. Repair mechanisms in prokaryotes are often not efficient enough to fix CRISPR-Cas induced DNA damage, and DNA breaks often result in cell death (Stern et al., 2010; Jiang et al., 2013; Vercoe et al., 2013; Gomaa et al., 2014). Nevertheless, many different examples exist in which a self-targeting spacer can be tolerated. Below we describe each known mechanism.

Active DNA repair

CRISPR-based targeting would be expected to induce irreparable damage, lest the cells repair invading genetic material and allow an infection to persist. Accordingly, many studies have

reported that chromosomal targeting by CRISPR nucleases is cytotoxic in different bacteria and archaea (Stern et al., 2010; Jiang et al., 2013; Vercoe et al., 2013; Bikard et al., 2014; Citorik et al., 2014; Gomaa et al., 2014; Li Y. et al., 2016). That said, there exist examples in which intrinsic DNA repair mechanisms such as homology-directed repair (HDR), non-homologous end joining (NHEJ), and alternative end-joining (A-EJ) mechanisms allow cell survival (Chayot et al., 2010; Tong et al., 2015; Cui and Bikard, 2016; Stachler et al., 2017; **Figure 2A**).

One potential mechanism is HDR through an additional copy of the chromosome. Cui and Bikard first observed this phenomenon when evaluating the consequences of targeting the *E. coli* chromosome with heterologously expressed Cas9 (Cui and Bikard, 2016). They found that targeting different sites within non-essential genes resulted in RecA-mediated HDR. Targeting did induce the SOS DNA-damage response, although the cells maintained their viability. In a separate example, Stachler and coworkers reported that the archaeon *Haloferax volcanii* could tolerate chromosomal targeting through its endogenous type I-B CRISPR-Cas system (Stachler et al., 2017). However, the tolerance could be attributed in part to the endogenous CRISPR array providing most of the crRNAs in the effector complexes. Deleting the Cas6 processing protein and expressing a mature self-targeting crRNA resulted in a fitness defect that was strengthened by expressing the crRNA at higher levels. The extent of self-targeting in the presence of the endogenous CRISPR array therefore was sufficiently weak to allow repair through HDR and the roughly 20 copies of the *H. volcanii* genome (Zerulla et al., 2014; Stachler et al., 2017). In both of these examples, there would likely be some selective pressure to disrupt self-targeting given the need for continuous repair.

Non-homologous end joining and alternative end-joining offer distinct repair mechanisms that permanently alter the target site, preventing further attack by CRISPR-Cas systems. NHEJ does not utilize a repair template and instead repairs double-stranded DNA breaks (DSBs) by adding insertions or deletions (indels) to the site of the DSB. Some prokaryotes possess relatively unsophisticated NHEJ machinery compared to eukaryotes, typically comprised of the complexes Ku and LigD (Aravind and Koonin, 2001; Weller et al., 2002; Gong et al., 2005; Bowater and Doherty, 2006; Shuman and Glickman, 2007; Tong et al., 2015). Some bacteria such as *E. coli* lacking Ku and LigD can utilize phage ligases to mediate NHEJ-like repair of CRISPR-Cas induced DSBs (Su et al., 2019). While NHEJ efficiently repairs DNA cleaved by some CRISPR nucleases in eukaryotic cells, some CRISPR-Cas induced DNA damage in prokaryotes is still highly cytotoxic when NHEJ is active (Xu et al., 2015; Bernheim et al., 2017). A-EJ is a repair mechanism that relies on microhomology-mediated end joining and largely leads to deletions. DSBs induce extensive end-resection that is mostly dependent on RecBCD, while Ligase-A repairs the break by joining micro-homologous regions of 1 to 9 bps (Chayot et

al., 2010; **Figure 2A**). Prior work suggested that A-EJ led to large deletions following genomic attack by a type I-F CRISPR-Cas system in *Pectobacterium atrosepticum* (Vercoe et al., 2013). Whether repair occurs through NHEJ or A-EJ, the resulting genome would be less susceptible (or even completely unsusceptible) to follow-up attack through the self-targeting spacer.

Figure 2: Surviving self-targeting. (A) Survival of CRISPR-Cas targeting by intrinsic repair mechanisms. The type II effector protein Cas9 is used as an example. The CRISPR effector complex binds to its target in the genome (red) next to a PAM (orange), leading to a double-stranded break (DSB) causing different outcomes. (i) Cell death occurs if the break is not repaired. (ii) Homology-directed repair (HDR) restores the target site in the presence of an intact copy of the chromosome. DNA ends of the DSB undergo trimming in a Rec-dependent manner. HDR leads to the restoration of a chromosome that undergoes further attack by the CRISPR-Cas system. (iii) Non-homologous end joining leads to the formation of an insertion or deletion (indel). End joining is mediated by the repair proteins Ku and LigD. (iv) Alternative end-joining leads to deletions. DNA ends are trimmed by RecBCD until micro-homologous regions (purple) are reached. These regions are then ligated by LigA, resulting in deletions. (B) Escape from autoimmunity through mutations, deletions, or active inhibition. (i,ii) mutations (yellow) or deletions within the protospacer, PAM or CRISPR array disrupts self-targeting. (iii) Mutation of the cas operon, inhibition of Cas expression or deletion of a cas gene or the entire locus can also prevent self-targeting. (iv) Anti-CRISPR proteins encoded within an integrated prophage can block CRISPR-Cas interference through different mechanisms, such as binding the Cas effector protein to prevent PAM recognition.

Mutations disrupting CRISPR-based targeting

Mutations can prevent efficient CRISPR targeting in multiple ways. One way is mutation of the target site such as through NHEJ or A-EJ, impacting spacer complementarity or PAM recognition (**Figure 2B**). Two studies evaluating self-targeting through type II-A systems in *S.*

thermophilus reported not only mutations of the targeted *lacZ* gene but also deletion of the gene (Selle et al., 2015; Cañez et al., 2019). In one of the studies assessing self-targeting in the *S. thermophilus* strain LMD-9, targeting resulted in loss of ~1.2 kb that included the *lacZ* gene. These deletions appeared to arise via genomic island excision via recombination between two flanking insertion-sequence elements (Selle et al., 2015) that occur quite frequently in *S. thermophilus* (Bolotin et al., 2004). In contrast, another study reported an ~40-kb deletion upon targeting *lacZ* in the *S. thermophilus* strain DGCC7710 that shares 99.2% sequence homology to LMD-9. No insertion-sequence elements could be detected within 50 kb flanking the *lacZ* gene, potentially explaining why the same escape mechanism observed in LMD-9 did not take place in DGCC7710. Recombination here might have happened between two regions encoding two *galE* genes sharing 86% nucleotide identity located 3 kb upstream and 30 kb downstream of *lacZ* (Cañez et al., 2019). One interesting possibility is that these large deletions existed in a small fraction of the cell population, where CRISPR-based targeting allowed this sub-population to survive (Selle et al., 2015; Cañez et al., 2019). The different outcomes of self-targeting in *S. thermophilus* LMD-9 and DGCC7710 highlight the different escape mechanisms that can occur even between strains of the same species.

Escape from lethal self-targeting can not only occur via target mutation but also via mutations or deletions within the CRISPR array or the *cas* genes (**Figure 2B**). In the same study noted above (Cañez et al., 2019), the authors also investigated the escape mechanism by targeting *lacZ* with the endogenous type I-E CRISPR-Cas system in *S. thermophilus* DGCC7710. Surprisingly, no deletions in the target site could be observed, and escape mutants consistently harbored defective plasmids missing the targeting spacer and one repeat likely caused by recombination between repeats that eliminated the self-targeting spacer (Cañez et al., 2019; **Figure 2B**). Thus, escape mechanisms can differ not only between strains but also between CRISPR-Cas systems. Loss of the plasmid-encoded spacer also occurred as the principal mode of escape when targeting *E. coli*'s genome with its endogenous type I-E system (Gomaa et al., 2014). Separately, as an example of disrupting *cas* genes, *Lactobacillus acidophilus* NCFM appears to have deleted its entire *cas* gene cassette to avoid lethal self-targeting by six genome-targeting spacers encoded in the CRISPR array (Stern et al., 2010; Kersey et al., 2018; Zhang et al., 2018). Furthermore, mutations in the *cas* genes were reported when targeting the staphylococcal cassette chromosome *mec* (SSC*mec*) in *Staphylococcus aureus* through the endogenous III-A CRISPR-Cas system (Guan et al., 2017) or when targeting different sites through the I-F CRISPR-Cas system native to *P. atrosepticum* (Dy et al., 2013). Between disruption of the spacer or *cas* genes, explicit loss of an endogenous self-targeting spacer has been less reported in natural systems. However, this can be explained

by bioinformatic searches having difficulties detecting loss of self-targeting spacers in genome databases given that the rest of the CRISPR array may still be intact.

Self-targeting by a CRISPR-Cas system also does not need to drive only one mode of escape. For instance, in the example of self-targeting through the type III-A CRISPR-Cas system in *S. aureus*, the authors reported different mutations or deletions in the escape mutants (Guan et al., 2017). Large deletions that included the target site occurred in ~90% of the escape mutants, while spacer mutations or loss-of-function mutations in *cas* genes were also detected. Separately, in the example of self-targeting through the type I-F CRISPR-Cas system in *P. atrosepticum*, the bacterium harbors one naturally occurring self-targeting spacer that is not cytotoxic due to a mutation in the target's PAM (Dy et al., 2013). Transformation of plasmids harboring other self-targeting spacers further led to different sized deletions of regions containing the protospacer or removal of the *cas* operon. The frequency of one escape mode over another likely depends on different factors such as the frequency of background mutation and recombination, the types of mutations that can form, and the fitness defect that they introduce.

Partially complementary spacers directing target binding but not cleavage

Mutations to the target site or the spacer can result in partial complementarity between spacers and their protospacers. For some systems, partial complementarity eliminates target cleavage but can preserve target binding. Comparison between off-target binding by dCas9 and off-target cleavage by Cas9 demonstrated extensive off-target binding but not cleavage (Wu et al., 2014). Another study also showed that partial target complementarity could allow an active Cas9 to bind but not cleave DNA, resulting in transcriptional silencing (Bikard et al., 2013). Wu and coworkers proposed a model which would explain the higher specificity of Cas9 by taking binding at the seed region into consideration. They hypothesized that PAM recognition by the Cas9:crRNA complex leads to DNA melting and enables base pairing between the spacer and the complementary seed region. As long as complementarity exists through the seed region, partial base pairing can allow target binding without cleavage (Wu et al., 2014). As a result, organisms could harbor spacers with partial complementarity to their own genome that would still drive target recognition but not autoimmunity.

RNA targeting

While we have focused on CRISPR-Cas systems that explicitly target DNA, the type III and VI systems naturally target RNA as part of immune defense (Hale et al., 2009, 2012; Abudayyeh et al., 2016), with distinct implications for self-targeting. Type III CRISPR-Cas systems are capable of targeting DNA and RNA. The system's Csm or Cmr effector complex is guided to

RNA targets complementary to the crRNA, triggering the sequence-specific RNase activity of Csm3 or Cmr4, respectively (Benda et al., 2014; Goldberg et al., 2014; Tamulaitis et al., 2014; Samai et al., 2015). Lack of complementarity between the 5' crRNA handle and the target RNA activates single-stranded DNase activity by Cas10 (Jung et al., 2015; Kazlauskienė et al., 2016), although there is evidence of a 3' RNA PAM motif that suggests diverging criteria for target selection across type III systems (Elmore et al., 2016). Furthermore, target recognition by the type III effector complex triggers Cas10 to produce cyclic adenylylates. These molecules in turn activate the CRISPR accessory protein Csm6/Csx1, leading to non-specific RNA degradation to assist in viral defense (Kazlauskienė et al., 2017; Niewoehner et al., 2017; Rouillon et al., 2018).

In contrast to type III CRISPR-Cas systems, type VI systems represent the only systems known to-date that exclusively target RNA (Abudayyeh et al., 2016). Cas13, the type VI effector protein, recognizes complementary RNA sequences as long as the repeat-portion of the crRNA cannot extensively base pair with the target (Meeske and Marraffini, 2018). Upon target recognition, Cas13 undergoes a conformational change that activates the effector's ribonuclease domain, resulting in non-specific cleavage of the proximal portions of the target RNA (Liu et al., 2017a,b). The effector domain remains highly active even after cleavage of local RNAs, leading to the extensive degradation of cellular RNAs. The degradation can be sufficiently extensive to shut down the host's growth, resulting in a reversible dormancy state (Abudayyeh et al., 2016; Meeske et al., 2019). The activity of type VI CRISPR-Cas targeting also had a more severe effect on the fitness of *E. coli* during high production of target RNA, potentially allowing the cell to survive self-targeting by Cas13 if the target RNA is not highly expressed (Abudayyeh et al., 2016) and sparing the cells from self-targeting induced dormancy.

Another consequence of RNA-based (self-)targeting is type III systems and Cas13 ignoring transcriptionally silent targets. Activation of type III and VI systems only upon RNA recognition would be particularly important for temperate phages and viruses whose lytic genes are repressed during lysogeny (Johnson et al., 1981). Therefore, if a spacer directs the Csm/Cmr effector complex or Cas13 to an RNA necessary for the lytic cycle, then only the lysogens entering the lytic cycle will be targeted. Tolerance of a prophage has been shown for the type III-A system in *Staphylococcus epidermidis* that actively targets its own prophages only upon transition into the lytic cycle (Goldberg et al., 2014). By only targeting phages and viruses in the lytic cycle, cells are able to maintain any potentially positive functions that might arise from a prophage/provirus encoded in their genome and prevent cell death during the invader's lytic phase.

Genome-encoded anti-CRISPR proteins

Escape from targeting is not limited to genetically disrupting the CRISPR-Cas system or its target; another means involves inhibiting CRISPR-Cas activity in *trans* by Acrs. These proteins allow phages/viruses to thwart immunity by CRISPR-Cas systems (Pawluk et al., 2018). So far, Acrs have been identified that inhibit different subtypes of type I, II, III, and V CRISPR-Cas systems (Bondy-Denomy et al., 2013; Pawluk et al., 2014, 2016a,b; Hynes et al., 2017; Rauch et al., 2017; He et al., 2018; Marino et al., 2018; Watters et al., 2018; Bhoobalan-Chitty et al., 2019), and Acrs against type IV and VI systems likely await discovery. The Acrs identified to-date have exhibited remarkable diversity in their sequence and in their mechanism of action, such as blocking DNA binding, preventing effector complex formation, sequestering the nuclease into dimers, blocking nuclease activity or preventing nuclease recruitment (Bondy-Denomy et al., 2015; Pawluk et al., 2018; Thavalingam et al., 2019).

Acrs allow phages and viruses to not only escape attack by CRISPR-Cas systems but also protect a lysogenized phage/provirus (not to mention the host chromosome) from an endogenous CRISPR-Cas system encoding a viral-targeting or chromosomal-targeting spacer (**Figure 2B**). Therefore, a genome encoding both a CRISPR-Cas system and a self-targeting spacer could potentially also encode an Acr. Rauch et al. (2017) hypothesized that self-targeting spacers would indicate the presence of an inhibiting Acr, which led them to identify four Acrs encoded in prophage regions of *Listeria monocytogenes* that inhibit Cas9. Separately, Watters et al. (2018) and Marino et al. (2018) used a similar approach to identify Acrs in *Moraxella bovoculi* active against type I and type V CRISPR-Cas systems. Given the success in identifying Acrs in prokaryotes harboring self-targeting CRISPR-Cas systems, this mechanism could principally explain the natural appearance of self-targeting spacers.

Self-targeting spacers underlying alternative functions of CRISPR-Cas systems

We have described how self-targeting spacers can be acquired and how cells can avoid the cytotoxic impact of self-targeting. In some of these cases, self-targeting could reflect an alternative function of the CRISPR-Cas system. Here, we describe different examples in which self-targeting has impacted the host or in which a mechanism has been reported that could impact host behavior, potentially foreshadowing an alternative function. These examples can be divided into four categories: genome evolution, RNA degradation, transcriptional repression, and foreign invaders co-opting self-targeting CRISPR-Cas systems. While conserved examples of CRISPR-Cas systems performing alternative functions have not been

described, there has been a steady increase in anecdotal examples that suggest that CRISPR-Cas systems can stray from adaptive immunity, with varying benefits to the host.

Genome evolution

One reported outcome of acquiring self-targeting spacers is genome evolution by forcing the host to mutate in order to escape autoimmunity. While this mechanism still reflects active DNA targeting through the standard steps of CRISPR-based immunity and thus may not represent a “true” alternative function, we still consider this an alternative function because of the large-scale change in genomic content that can confer benefits to the host. Specifically, chromosomal targeting can lead to mutations or small deletions in the target gene. These deletions can also be much larger and encompass many surrounding non-targeted genes. While any loss of an essential gene would be lethal, these larger deletions could also provide a fitness advantage by generating new phenotypes or reducing the overall size of the genome, and remodeling of pathogenicity islands could cause a change in bacterial virulence (Vercoe et al., 2013; Westra et al., 2014). Besides triggering active mutations, self-targeting by CRISPR-Cas systems can also select for a small sub-population already lacking the target (Dy et al., 2013; Selle et al., 2015).

Self-targeting by CRISPR-Cas systems can further lead to bacterial or archaeal evolution by disrupting an important gene and forcing the organism to adapt to this change. One important example comes from the bacterium *Pelobacter carbinolicus*. Unlike other members of the *Geobacteraceae* family, *P. carbinolicus* cannot reduce Fe(III) as part of its metabolism (Richter et al., 2007). This phenotype is potentially caused by an existing spacer within the endogenous type I-E CRISPR-Cas system that is complementary to a region within the histidyl-tRNA synthetase gene *hisS*. A lack of histidyl-tRNA synthetase would lead to reduced translation of proteins with multiple closely spaced histidines. The *hisS*-targeting spacer is located opposite of the end of the CRISPR array where new spacers are added, suggesting that the uptake of this spacer did not occur recently. Supporting the active targeting of *hisS*, transforming the self-targeting spacer and the *hisS* gene from *P. carbinolicus* into a genetically tractable strain of the related species *Geobacter sulfurreducens* resulted in few transformants, and these transformants grew poorly. *P. carbinolicus* has also lost or mutated multiple genes with high histidine content that are still present in closely related species, potentially also explaining the loss of Fe(III)-respiration (Aklujkar and Lovley, 2010). It would be interesting to see how the endogenous I-E system is impacting HisS expression without driving lethal autoimmunity, where we expect the mechanism to fall under one of the categories below.

CRISPR-Cas induced mRNA cleavage

Not all CRISPR-Cas systems solely target DNA, wherein RNA targeting could modulate gene expression without inducing cytotoxicity. To-date, type III, type VI, some type I, and some type II CRISPR-Cas systems have been shown to target RNA (Hale et al., 2009, 2012; O'Connell et al., 2014; Samai et al., 2015; Abudayyeh et al., 2016; Li R. et al., 2016; Dugar et al., 2018; Rousseau et al., 2018; Strutt et al., 2018). In the event that RNA but not DNA is targeted, self-targeting spacers would not necessarily result in autoimmunity but instead could degrade mRNA and lead to changes in gene expression.

The type III-B CRISPR-Cas system in *Myxococcus xanthus* is a potential example that degrades mRNA, although this mechanism remains to be fully established (Wallace et al., 2014). As part of the study, the authors performed a transposon screen in a $\Delta pilA$ strain lacking the type IV pilus required for exopolysaccharide production. They isolated a mutant with a transposon inserted into the CRISPR3 array, which coincided with restored exopolysaccharide production and impaired fruiting body development. Wallace et al. (2014) proposed a mechanism in which the transposon enhanced pre-crRNA processing, leading to crRNA-dependent regulation of exopolysaccharide production and fruiting body development. Other possibilities are that the repertoire of crRNAs includes a portion of the transposon, altering the targeting potential of the array. Given more recent reports of type III-B systems targeting transcriptionally active DNA (Peng et al., 2015; Estrella et al., 2016), other mechanisms may be at work in *M. xanthus* harboring the transposon insertion.

Another alternative function via self-targeting that appears to involve mRNA degradation allows the pathogen *Pseudomonas aeruginosa* to evade immune detection (**Figure 3**). The type I-F system in *P. aeruginosa* strain UCBPP-PA14 encodes one spacer within its CRISPR1 array that bears partial complementarity to the chromosomally encoded *lasR* gene. LasR is a bacterial quorum sensing regulator whose regulon includes virulence-associated factors presumably detected through Toll-like receptor 4 in mammals. The self-targeting spacer did not lead to any detectable cleavage of the chromosomal DNA but instead appeared to cleave the *lasR* mRNA. Downregulation of this receptor in turn led to a reduced pro-inflammatory response. The suspected target within the *lasR* mRNA spans 12 nts, with one internal mismatch and base pairs with the 3' end of the spacer. Mutational analysis further revealed that disrupting a 5'-GGN-3' sequence immediately upstream of the *lasR* target as well as the following 8 base pairs blocked mRNA target degradation (Li R. et al., 2016).

As a brief follow-up to this study, Müller-Esparza and Randau searched for other potentially targeted mRNAs within the *P. aeruginosa* UCBPP-PA14 strain based on potential target sites that include the upstream 5'-GGN-3' sequence followed by nine complementary nts. They

could identify 189 putative targeted mRNAs, suggesting that additional requirements such as mRNA secondary structure are needed for mRNA targeting. Therefore, further studies are necessary to clarify the requirements for mRNA degradation by the type I-F CRISPR-Cas system in this strain of *P. aeruginosa* and the many other organisms encoding these systems (Müller-Esparza and Randau, 2017).

Figure 3: Examples of alternative CRISPR-Cas functions. The type I-F CRISPR-Cas system in *P. aeruginosa* harbors two CRISPR arrays that account for two different alternative functions. The left side shows partial binding between a crRNA derived from the CRISPR1 array and the *lasR* mRNA, with an indispensable interaction region of 8 nts (turquoise). The Cas effector complex (brown) binds to the target region with an adjacent recognition motif (orange), with some involvement of the Cas3 nuclease. *lasR* mRNA is then degraded, leading to reduced host recognition by Toll-like receptor 4 during an infection. The right side shows partial binding of a crRNA derived from the CRISPR2 array to a prophage region. Binding by the Cas effector complex recruits Cas3, resulting in nicking of one strand of the target DNA. Recognition by RecA triggers intrinsic processes that lead to induction of SOS-regulated, phage-related genes that lead to cell death of cells specifically forming a biofilm, while planktonic cells are unaffected.

Cas9 is traditionally seen as a DNA-targeting nuclease, yet emerging examples have revealed that some Cas9s can also target RNA (O'Connell et al., 2014; Rousseau et al., 2018; Strutt et al., 2018). Original studies of the Cas9 from *Streptococcus pyogenes* suggested that the effector protein could differentiate between RNA and DNA (Gasiunas et al., 2012), wherein RNA targeting could only be achieved by hybridizing RNA with a PAM-presenting oligonucleotide (PAMmer) (O'Connell et al., 2014; Nelles et al., 2016). Later, it was shown that some Cas9 proteins can cleave RNA even in the absence of a PAMmer. Specifically, the Cas9 from the type II-C system in *Neisseria meningitidis* was shown to cleave RNA *in vitro*, while

Cas9 from the type II-A system in *S. aureus* and the type II-C system in *C. jejuni* were shown to cleave RNA *in vitro* and *in vivo* (Dugar et al., 2018; Rousseau et al., 2018; Strutt et al., 2018). In all of these cases, RNA targeting did not require a flanking recognition motif. In the example from *C. jejuni*, the naturally occurring spacers were shown to bind and, in some cases, drive Cas9-mediated cleavage of endogenous RNAs. These spacers only exhibited partial complementarity to their targets, and the associated DNA sequences were not flanked by recognized PAMs, preventing genome cleavage. Dugar and coworkers did not explicitly identify a phenotype associated with RNA targeting by the endogenous Cas9 (Dugar et al., 2018), although Strutt et al. (2018) demonstrated that the Cas9 from *S. aureus* could inhibit gene expression through programmable RNA targeting in *E. coli* without leading to cell death. The above mentioned examples show that some DNA targeting systems can also target RNA, with the potential for these same systems to modulate gene expression by RNA degradation in their native hosts.

CRISPR-Cas induced DNA damage response

The type I-F CRISPR-Cas system in *P. aeruginosa* UCBPP-PA14 performs a distinct alternative function that induces the SOS response, preventing biofilm formation and impairing swarming motility (Zegans et al., 2009; Cady and O'Toole, 2011). A key factor was the presence of a partial match between a spacer within the CRISPR2 array and a sequence present within the lysogenized phage DSM3 (**Figure 3**). The authors showed that the observed phenotype was dependent not on the presence of the lysogenized phage but rather solely on the target sequence. The presence of the CRISPR-Cas system and the PAM-flanked protospacer led surface-attached cells to undergo cell death, explaining the lack of biofilm formation. The proposed mechanism-of-action involved the recruitment of Cas3 upon binding of the Cascade-crRNA complex to the region of partial complementarity, which recruited RecA and activated the SOS response upon nicking of one DNA strand. Activated RecA also triggered a pathway that led to accumulation of phage-related genes that induced cell death upon surface attachment (Heussler et al., 2015). The ensuing questions are whether this same phenomenon can be found in other biofilm-forming bacteria and whether partial genome targeting can induce other phenotypes.

Transcriptional regulation

Beyond RNA targeting, CRISPR-Cas systems have the potential to regulate transcription through partial spacer complementarity or due to the presence of an inactivated nuclease (Sampson et al., 2013, 2019; Ratner et al., 2019). Partial complementarity resulted in regulation of transcription in *Francisella novicida* by so-called scaRNAs (small CRISPR/Cas-

associated RNAs). ScaRNAs were encoded close to the CRISPR array associated with the type II CRISPR-Cas system in *F. novicida*. Strictly speaking, the scaRNA-based mechanism is not dependent on a self-targeting spacer but rather on the scaRNA acting as a crRNA. Originally it was hypothesized that the scaRNA targets RNA (Sampson et al., 2013), but later it was shown that the scaRNA hybridizes with the tracrRNA and directs Cas9 to the partially complementary 5' UTR of its endogenous DNA targets. DNA binding of the target results in transcriptional repression (Ratner et al., 2019; Sampson et al., 2019). In the case of *F. novicida*, targeting with the scaRNA-tracrRNA-Cas9 complex resulted in transcriptional repression of four genes contributing to its virulence by facilitating evasion from immune detection. DNA cleavage by Cas9 is prevented through only partial complementarity of the scaRNA to the target site (Ratner et al., 2019).

Aside from transcriptional repression by DNA binding near promoter regions, another means to regulate transcription is through disruption of the Cas nuclease's active site. This phenomenon can occur in type I systems that lack the effector protein Cas3 but have an intact Cascade complex (Luo et al., 2015). It is also possible to disrupt the nucleolytic activity of a Cas effector protein by mutating the active site. For example, alanine substitutions in the HNH and RuvC domains in the single effectors Cas9 or Cas12a result in a catalytically dead protein that can bind a target but not cleave it (Bikard et al., 2013; Qi et al., 2013; Leenay et al., 2016). While mutations that solely inactivate cleavage are much less likely than deleterious mutations to the nuclease, either means would result in CRISPR machinery that tightly binds DNA, thereby blocking transcription. Natural examples of catalytically dead CRISPR-Cas systems acting as gene regulators have not been reported, although the ease in disrupting *cas3* in the highly prevalent type I systems would suggest that nature has regularly sampled this alternative function. Screening for CRISPR-Cas systems harboring inactive nucleases and self-targeting spacers or spacers with partial complementarity to the genome might lead to the discovery of further CRISPR-based gene regulatory systems.

Invaders co-opting CRISPR-Cas self-targeting

There is also evidence of foreign invaders co-opting CRISPR-Cas systems to either promote the spread of MGEs or weaken the host's adaptive immunity through self-targeting spacers. Recent publications described CRISPR-Cas systems associated with Tn7-like transposons that led to spacer-directed insertion of the transposon (Peters et al., 2017; Klompe et al., 2019; Strecker et al., 2019). The transposon portion of the system generally consists of *tnsB*, *tsnC*, and *tniQ* (a *tnsD* homolog), yet it lacks *tnsD* and *tnsE* normally responsible for recognition of the attachment site (Waddell and Craig, 1988, 1989). Instead, the CRISPR-Cas portion of the system, which lacks nuclease activity and the acquisition machinery, directs transposon

insertion up to ~80 nts downstream of the target site. Because the target site is preserved, an integrated CRISPR transposon would inherently encode a self-targeting spacer (Klompe et al., 2019; Strecker et al., 2019). Nevertheless, the self-targeting spacer appears to be no longer functional due to the lack of multiple transposon insertions at the same target site (Strecker et al., 2019). Acquiring different spacers targeting within the bacteria's genome would allow the transposon to insert itself elsewhere in the genome, although it is not known how new spacers can be acquired due to the lack of acquisition machinery.

Beyond transposons, phages and viruses also represent types of mobile genetic elements that have co-opted CRISPR-Cas systems for their own purposes. It is reported that some phages or viruses harbor at least parts of CRISPR-Cas systems (Seed et al., 2013; Hooton and Connerton, 2014; Krupovic et al., 2015; Lvasseur et al., 2016; Hudaiberdiev et al., 2017; Naser et al., 2017; Dou et al., 2018). One noteworthy example comes from the lysogenic CP8/CP30A phage in *C. jejuni* described earlier. This phage encodes a *cas4*-like gene that is responsible for spacer acquisition within the type II-C CRISPR-Cas system targeting the host's genome. The authors hypothesized that these self-targeting spacers might provide a benefit for the phage infecting *C. jejuni* and assist in phage-mediated escape from CRISPR attack (Hooton and Connerton, 2014). Phages and viruses could escape from the host immune system by forcing the organism to use its endogenous CRISPR-Cas system for autoimmunity rather than for attacking viral invaders. Furthermore, the organism might mutate or delete its CRISPR-Cas system to prevent cell death and with this also lose the ability to target invading phages or viruses. In total, these examples show that the host and its invaders can utilize CRISPR-Cas systems and their encoded self-targeting spacers for different purposes.

Conclusion and future perspectives

Self-targeting spacers occur surprisingly often in nature, albeit less frequently than spacers matching sequences from known phages, viruses or plasmids. The apparent paradox between the presence of these spacers and their presumed autoimmunity can be resolved in two general ways. These spacers could represent less frequent but important biological "accidents" that compel cells to reduce or eliminate the impact of self-targeting. Alternatively, the cells could be actively using these self-targeting spacers for other purposes that extend beyond adaptive immunity. Both have been reported in the literature, with only a few examples of the latter. However, alternative functions through self-targeting spacers represent an underexplored area of research in CRISPR biology that could yield exciting new insights and tools. Below, we describe multiple opportunities for future research to uncover further instances of alternative functions, advance our understanding of CRISPR biology and evolution, and expand the available toolbox of CRISPR technologies.

One potential focus of future work is on CRISPR-Cas systems encoding multiple self-targeting spacers or on organisms encoding multiple CRISPR-Cas systems. A few examples of bacteria and archaea encoding self-targeting spacers have been reported (Stern et al., 2010) but never explored experimentally. While these examples were categorized as non-effective targeting due to the lack of an apparent PAM, mutated adjacent repeats, extended base pairing with the repeat or lack of some *cas* genes, these sequences could lead to some level of targeting. For instance, CRISPR nucleases are increasingly known to recognize non-canonical PAM sequences (Leenay and Beisel, 2017), and the absence of some *cas* genes could still allow some functions. The accumulation of multiple self-targeting spacers would also suggest a positive selective pressure. One exception could be the disruption of all but Cas1 and Cas2, possibly resulting in acquisition without negative selection against self-targeting spacers. The occurrence of prokaryotes with multiple CRISPR-Cas systems suggests the possibility that some systems could fulfill the canonical CRISPR function as an adaptive immune system and the others might perform alternative functions.

Another potential focus of future work is identifying spacers exhibiting partial complementarity to the host's genome. As described above, many CRISPR-Cas systems can still bind but not cleave partially complementary targets, resulting in transcriptional repression. Partial complementarity would also allow RNA targeting by some effector proteins, potentially allowing post-transcriptional regulation of endogenous genes. Standard searches for protospacers readily exclude partially matching sequences, owing in part to the difficulty in eliminating false positives. However, regardless of the source of these spacers, partial complementarity with the genome could drive alternative functions. More work is needed to understand what types of mismatches allow different CRISPR-Cas systems to bind but not cleave their targets. This information could then be fed into search algorithms tasked with identifying targets as potential sources of CRISPR-Cas systems moonlighting as gene regulators.

Anti-CRISPR proteins could also provide a potential source for alternative functions. As described above, one strategy to find new anti-CRISPR proteins is to identify organisms with self-targeting spacers (Rauch et al., 2017; Watters et al., 2018). However, the search could be reversed: identifying organisms that harbor both Acrs and CRISPR-Cas systems as potential candidates for identifying systems exhibiting alternative functions. For instance, an encoded Acr that blocks cleavage but not binding activity of the nuclease could convert the immune system into a transcriptional regulator (Pawluk et al., 2018). Discovering new Acrs still remains a major challenge, although further discoveries will enable the search for Acrs tied to alternative functions.

Beyond the discovery of novel instances of functions extending beyond adaptive immunity, interrogating how CRISPR-Cas systems exhibit alternative functions and cope with self-targeting continues to open new biotechnological applications. For instance, the recently discovered CRISPR transposons encoding genome-targeting spacers can serve as powerful tools to insert genes (Klompe et al., 2019; Strecker et al., 2019). Genome-targeting spacers have also been used with classical CRISPR-Cas systems to generate large deletions, representing important capabilities for genome engineering and minimization (Jiang et al., 2013; Oh and van Pijkeren, 2014). As there exist other means by which cells can escape autoimmunity, steps may be necessary to ensure target deletion is the predominant mode of escape. Beyond genome editing, self-targeting with endogenous CRISPR-Cas systems can be part of programmable gene regulation. The endogenous system can be rendered cleavage-deficient while preserving DNA binding activity (Luo et al., 2015). Efforts to interrogate escape from self-targeting have also revealed that gene regulation can be achieved without altering the endogenous system, such as by employing Acrs that inhibit cleavage activity but not DNA binding or by expressing partially complementary spacers. Finally, insights into self-targeting lend to employing endogenous CRISPR-Cas systems as programmable antimicrobials. If the endogenous system is fully active, self-targeting spacers can be used to kill specific bacteria (Bikard et al., 2014; Citorik et al., 2014; Gomaa et al., 2014). If the endogenous system is inhibited by an Acr, relieving expression or activity of these Acrs could unleash lethal autoimmunity, particularly if the endogenous system acquired self-targeting spacers. Further efforts to discover and elucidate new alternative functions could inspire the next generation of CRISPR technologies, emphasizing the need to further investigate the role of self-targeting CRISPR-Cas systems.

Wimmer, F., Englert, F., & Beisel, C. L. (2022). A TXTL-Based Assay to Rapidly Identify PAMs for CRISPR-Cas Systems with Multi-Protein Effector Complexes. In *Cell-Free Gene Expression* (pp. 391-411). Humana, New York, NY.

Abstract

Type I CRISPR-Cas systems represent the most common and diverse type of these prokaryotic defense systems and are being harnessed for a growing set of applications. As these systems rely on multi-protein effector complexes, their characterization remains challenging. Here, we report a rapid and straightforward method to characterize these systems in a cell-free transcription-translation (TXTL) system. A ribonucleoprotein complex is produced and binds to its target next to a recognized PAM, thereby preventing the targeted sequence from being cleaved by a restriction enzyme. Selection for uncleaved targeted plasmids leads to an enrichment of recognized sequences within a PAM library. This assay will aid the exploration of CRISPR-Cas diversity and evolution and help contribute new systems for CRISPR technologies and applications.

Introduction

CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats)-Cas (CRISPR-associated) systems are adaptive immune systems present in many bacteria and most archaea [1, 2]. Adaptive immunity is conducted in three general steps: acquisition, expression, and immunity. In the first step (acquisition), foreign DNA or RNA is recognized, and short fragments, called protospacers, are integrated into the CRISPR array as spacers separated by conserved repeats [3]. The selected protospacers are normally flanked by a protospacer adjacent motif (PAM) unique to each system and used to differentiate the invader-associated sequence from the spacer integrated into the CRISPR array [4, 5]. In the second step (expression), CRISPR arrays are transcribed and processed into mature CRISPR RNAs (crRNAs) [6]. These crRNAs then form a complex with the Cas effector nuclease. In the third

step (immunity), the resulting ribonucleoprotein complex screens DNA or RNA present in the cell for sequences complementary to the spacer and flanked by the PAM [7]. Upon recognition, the complex cleaves the recognized target through different mechanisms, completing the CRISPR-Cas system's task as an adaptive immune system [8].

Despite the three general steps of adaptive immunity, CRISPR-Cas systems are highly diverse. To-date, two classes, six types, and more than 30 subtypes have been classified. class I and II systems are divided based on the presence of a multi-protein effector complex or a single-effector protein, respectively [9]. Type I systems are part of class I and represent the majority of all CRISPR-Cas systems, yet remain understudied compared to class II systems. This is in part due to type I systems involving four to eight proteins in the effector complex at different stoichiometries (**Figure 1A**). Almost all of these proteins form a complex with the crRNA called Cascade (CRISPR-associated complex for antiviral defense) and screen invading DNA for its target. Upon target recognition, Cas3 is recruited to nick the non-target strand and processively degrade this strand in the 3'-to-5' direction [10, 11]. While harnessing this complex as a technology is far more challenging than harnessing a class II single-effector protein (e.g., Cas9 from type II systems), applications with type I CRISPR-Cas systems are now emerging. In particular, type I systems have been employed for genome editing and gene regulation in bacteria, archaea, and eukaryotes or as tailored-spectrum antimicrobials against bacterial pathogens [12–28]. To further explore the extensive diversity of CRISPR biology and advance the existing suite of CRISPR technologies, there is an opportunity to accelerate the characterization of type I systems.

Cell-free transcription-translation (TXTL) systems offer a convenient way to rapidly characterize CRISPR-Cas systems. TXTL systems are typically based on an *E. coli* cell lysate with the transcriptional and translational machinery being retained. With TXTL, DNA can be added to produce RNAs and proteins in minutes to hours, allowing for subsequent biochemical assays without protein purification or cell culturing [29]. So far, TXTL-based methods have been established to characterize the expression and immunity steps of CRISPR [30–33]. CRISPR arrays are efficiently transcribed and processed in TXTL, and processing can be visualized via northern blotting or RNA-Seq analyses [30, 31]. The targeting activity of Cas nucleases and crRNAs can also be assessed with TXTL by directing the CRISPR effector complex to target a fluorescence reporter plasmid, inhibiting fluorescence production [32, 33]. Targeting activity can also be used to screen for anti-CRISPR proteins (Acrs) that inhibit different steps of CRISPR immunity [33–37]. Within these various characterization approaches, arguably the most important is determining the PAM. A number of *in vivo* and *in vitro* PAM determination methods have been reported [38], although they have typically been limited to single-effector nucleases. Here, we report a binding-based PAM assay in TXTL that

is well suited for multi-subunit CRISPR effectors [46]. This assay differs from our previously performed TXTL-PAM assay [33, 39], as it relies on target binding rather than cleavage. Furthermore, the assay enriches rather than depletes recognized PAM sequences, reducing the required sequencing depth to identify even weakly recognized PAMs. Overall, the reported PAM assay enables a fast and easy method to rapidly determine PAM requirements of CRISPR-Cas systems with multi-protein effector complexes.

Figure 1: (A) Overview of DNA targeting with type I CRISPR-Cas systems. The type I-E CRISPR-Cas system from *E. coli* is used as a representative example. The *cas* genes encoding the proteins that form the Cascade complex are encircled in orange. The genes responsible for spacer acquisition are encircled in gray. As part of adaptive immunity, the system expresses the Cas proteins and transcribes the CRISPR array. The transcribed array is then processed into individual crRNAs that form a multi-protein ribonucleoprotein complex called Cascade. This complex screens DNA for protospacers comprising complementary sequences to the spacer (blue) and flanked by a PAM (purple). After Cascade binds a protospacer, it recruits Cas3 (green) to degrade the DNA. When the target is located in an invader such as a phage, recognition leads to DNA degradation and clearance of the invader. **(B)** Overview of the TXTL-based PAM determination assay. As part of the assay, three sets of plasmids are added to the TXTL mix: a plasmid encoding a PAM library (pGFP-PaCl-5N) next to a targeted sequence (gray) that contains a restriction enzyme (RE) recognition site (blue), plasmids encoding for Cascade (pEcCas8, pEcCse2, pEcCas7, pEcCas5, pEcCas6) and a plasmid encoding a crRNA (pEc-crRNA1). The ribonucleoprotein complex (orange) is produced and binds to targets flanked by a recognized PAM. A subsequent digestion step with the RE results in cleavage of target sequences not bound by Cascade. Proteinase K (brown) is then used to remove all proteins. Adapters for NGS are added to the undigested PAM-containing plasmids by PCR. NGS sequencing results in the enrichment of recognized PAMs in the digested samples in comparison to samples without RE digestion

Materials

Reagents and Kits

1. 3 M sodium acetate, pH 5.2: 3 M sodium acetate, adjust pH with CH₃COOH.
2. 70% ethanol (EtOH): prepare EtOH solution in dH₂O by measuring EtOH and dH₂O separately before combining.
3. Arbor Biosciences myTXTL Sigma 70 Master Mix kit.
4. LB-medium: 1% tryptone, 0.5% yeast extract, 86.6 mM NaCl, autoclave solution.
5. NGS library purification kit (e.g., AMPure beads).
6. Nuclease appropriate for NGS library preparation.
7. PCR purification kit.
8. Plasmid Midiprep kit.
9. Proteinase K (20 mg/μL).
10. Restriction enzyme (here PacI).
11. SOC medium: SOB medium, 10 mM MgCl₂, 20 mM glucose, sterilize by passing solution through a 0.2 μm filter.
12. SOB medium: 2% tryptone, 0.5% yeast extract, 8.6 mM NaCl, 2.5 mM KCl, adjust pH to 7.0 with 5 N NaOH, autoclave solution.

Equipment

1. 96-well V bottom plate.
2. Cover mat for 96-well plate.

Methods

This binding-based PAM assay in TXTL results in an enrichment of positive PAMs (**Figure. 1B**). The CRISPR-Cas multi-protein complex is expressed, and the crRNA is transcribed. An effector complex is formed and binds at its target region flanked by recognized PAMs within a PAM library. Thus, the targeted plasmid is protected from digestion of a restriction enzyme (RE) (here PacI) that has its recognition site within the crRNA complementary region. The TXTL reaction is then digested with the RE, and a proteinase K digestion is performed. The remaining DNA is extracted by ethanol precipitation and sent for next-generation sequencing (NGS). We also provide a protocol for a quality check with Sanger sequencing or quantitative PCR (qPCR) before sending the samples for NGS. Finally, we provide an example by

characterizing the PAM requirements for the well-known *E. coli* Type I-E CRISPR-Cas system. All plasmids and primers that are used are stated in **Tables 1** and **2**, respectively.

Table 1: List of plasmids used

PAM library construction

The PAM library should be at least one nucleotide longer than the expected PAM. We use five nucleotides (1024 combinations) in the example here, as the demonstration system from *E. coli* traditionally has a 3-nt PAM. For the PAM library, choose a plasmid with a unique RE recognition site within an untranscribed region. Our construct utilizes a unique restriction site recognized by *PacI* and additionally encodes for deGFP (pGFP-*PacI*). Make sure the RE can be heat inactivated. If introduction of a unique RE recognition site is necessary, this can be done by PCR mutagenesis of the chosen plasmid with primers including the recognition site at the 5' end of either one or both primers followed by circularization and template removal such as with a Kinase-Ligase-DpnI (KLD) enzyme mix (see **Notes 1** and **2**).

The region targeted by the CRISPR-Cas system of interest should be chosen to span the RE recognition site. The PAM library (pGFP-*PacI*-5N) is then constructed adjacent to the targeted region (**Figure 2A**). For introduction of the PAM library, mutagenic primers are used (pr-01, pr-02) that amplify the whole plasmid at the desired site and include randomized nucleotides at their 5' end. The resulting PCR product is then circularized, and the original DNA template is removed, such as with a Kinase-Ligase-DpnI (KLD) enzyme mix (see **Note 1**).

1. Transform library construct (pGFP-*PacI*-5N) in competent *E. coli*.
2. Recover transformed cells in 1 mL SOC medium without antibiotics for 1 h.
3. Add the recovered cell suspension in 50 mL LB medium with appropriate antibiotics and incubate overnight at an appropriate temperature.
4. Use a plasmid Midiprep kit to isolate the library plasmid from the 50 mL culture.
5. Re-clean and concentrate the plasmid DNA, if necessary, by a PCR purification kit.
6. Amplify the library plasmid (pGFP-*PacI*-5N) with primers spanning the PAM library (pr-03, pr-04) and send for Sanger sequencing to check for library quality (**Figure 2B**).

Figure 2: Construction of the PAM library and crRNA expression construct. (A) Overview of the PAM library containing plasmid (pGFP-Pacl-5N). The PAM (red) consists of five random nucleotides and is located upstream of the protospacer (gray) that includes the RE recognition site (blue). Primers for library construction (pr-01, pr-02) are shown in brown. (B) Preliminary check of PAM library cloning by Sanger sequencing. To verify the cloned PAM library, a region containing the PAM library is amplified (primers are shown in brown) (pr-03, pr-04) and sent for Sanger sequencing. A representative sequencing trace is shown with nucleotide peaks. Below: a zoomed-in view of the library region. The nucleotide distribution does not need to be entirely equal, as enriched sequences are normalized to sequences in undigested samples as part of the NGS analysis. (C) The designed array sequence (pEc-crRNA1) from the I-E system in *E. coli* that is designed to target the PAM library-flanked target. The array is flanked by an upstream promoter and a downstream terminator. Repeats are shown in dark gray and the spacer is shown in light gray. The crRNA spacer spans the RE recognition site (blue).

CRISPR-Cas plasmid design and preparation

Cas proteins that form the Cascade can either be cloned on separate plasmids each (pEcCas8, pEcCse2, pEcCas7, pEcCas5, pEcCas6) or as an operon on one plasmid (see **Notes 3** and **4**). Use a protein expression vector with a strong promoter, an appropriate ribosomal binding site, and a terminator as the backbone (see **Note 5**). CRISPR arrays are cloned as a repeat-spacer-repeat (pEc-crRNA1) with a strong promoter and flanked by a terminator (**Figure 2C**). The spacer sequence herein is identical to the sequence downstream of the PAM library, covering the RE-recognition site. Transform all plasmids in competent *E. coli* and isolate the plasmids with a plasmid Midiprep kit followed by a PCR purification step.

PAM Assay

1. Prepare TXTL reaction on ice (**Table 3**) (see **Note 8**).
2. Carefully vortex the reactions and spin them down shortly.
3. Incubate at 29°C for 16 h (see **Notes 8** and **9**).
4. Dilute 3 μL of the TXTL reaction in 1.197 μL of nuclease-free water (see **Note 10**).
5. Prepare RE digestion reaction (**Table 4**), always prepare a control reaction with nuclease-free water instead of the RE.
6. Digest for 1 h at appropriate temperature (37°C for Pacl).
7. Heat inactivate RE (20 min at 65°C for Pacl).
8. Prepare proteinase K digestion (**Table 5**) and incubate for 1 h at 45°C.
9. Inactivate proteinase K for 5 min at 95°C.

Table 3: Components for the TXTL reaction of the PAM determination assay

| Component | Volume (μL) | Initial concentration (nM) | Final concentration (nM) |
|----------------------------------------------------------------------------------------------------|--------------------------|----------------------------|--------------------------|
| TXTL | 4.5 | - | - |
| <i>E. coli</i> Cascade plasmids (pEcCas8, pEcCse2, pEcCas7, pEcCas5, pEcCas6) (see Note 7) | 0.4 | 45 | 3 |
| crRNA plasmid (pEc-crRNA1) | 0.5 | 12 | 1 |
| PAM library plasmid (pGFP-Pacl-5N) | 0.4 | 15 | 1 |
| IPTG | 0.06 | 50,000 | 500 |
| T7RNAP (pT7RNAP) | 0.1 | 12 | 0.2 |
| Water | 0.04 | - | - |

Table 4: Components for the RE digestion reaction

| Component | Volume (μL) | Initial concentration | Final concentration |
|------------------|--------------------------|-------------------------|---------------------------|
| TXTL dilution | 500 | - | - |
| RE Buffer | 56.1 | 10x | 1x |
| RE (Pacl)/ water | 5 | 10 units/ μL | 0.09 units/ μL |

Table 5: Components for the Proteinase K digestion reaction

| Component | Volume (μL) | Initial concentration (mg/mL) | Final concentration (mg/mL) |
|--------------------|--------------------------|-------------------------------|-----------------------------|
| Digestion reaction | 561.1 | - | - |
| Proteinase K | 1.4 | 20 | 0.05 |

DNA extraction

DNA is extracted by EtOH precipitation (see **Note 11**). All centrifugation steps are done at maximum speed and at 4°C.

1. Divide each sample in two equal parts of 280 μL so the following EtOH precipitation can be carried out in 1.5-mL tubes.
2. Add 3 M sodium acetate, pH 5.2 and ice-cold 100% EtOH to your samples (**Table 6**).
3. Mix by vortexing and spin down quickly.
4. Immediately store at -80°C in a pre-cooled rack for at least 20 min (see **Note 12**).
5. Spin your samples for 15 min (see **Note 13**).
6. Carefully remove liquid by decanting.
7. Add 200 μL of ice-cold 70% EtOH to your samples.
8. Spin for 10 min (see **Note 13**).
9. Repeat steps 6–8.
10. Remove liquid completely with a pipette, being careful to not touch the side of your tube with the DNA pellet.
11. Evaporate the remaining liquid by placing the tube at 50°C with an open lid.
12. Add 10 μL of nuclease-free water to the tube, be careful not to touch the pellet.
13. Incubate at 65°C for 10 min.
14. Vortex vigorously.
15. Combine your divided samples.

Table 6: Components for ethanol precipitation reaction

| Component | Volume (μL) |
|---------------------------------|------------------------------------------|
| Proteinase K digestion reaction | 280 |
| 100% EtOH, ice-cold | 700 |
| 3M sodium acetate, pH 5.2 | 28 |

Quality check

The final output of the PAM assay requires NGS. However, there are some methods to estimate if the assay was successful and that provide some indication of the expected PAMs. Specifically, Sanger sequencing of the PAM library containing region gives indication of the recognized PAMs if compared to sequencing results of samples lacking RE-digestion. Analysis of protection of RE-digestion by qPCR can provide an idea if the Cascade-crRNA complex was able to bind to its target.

Sanger sequencing

1. PCR-amplify a region containing the PAM library from the targeted plasmid in the digested and the undigested (control) sample (pr-03, pr-04).
2. Use a PCR purification kit to purify the amplicons.
3. Send the amplicons for Sanger sequencing using one or both primers used for amplification.
4. A noticeable difference in the sequencing results within the PAM library region between the digested and undigested samples indicates recognition of specific PAMs and thus enrichment of the recognized PAMs in the Sanger sequencing file (**Figure 3A**).

Figure 3: Preliminary assessment of a PAM assay readout. (A) Preliminary assessment by Sanger sequencing. An amplicon is generated from the targeted plasmid (pGFP-PacI-5N) that includes the PAM library region (red) and the targeted region (gray) with the RE recognition site (blue). Primers (pr-03, pr-04) are shown in brown. The nucleotide peaks from Sanger sequencing are shown for a sample that was digested with PacI and a sample that was not digested with PacI. The digested sample shows some increased peaks compared to the undigested sample, suggesting successful PAM recognition during the PAM assay. (B) Preliminary assessment with qPCR. The relative amount of uncleaved DNA in a digested sample is compared to the undigested control. The fraction of protected DNA is then determined based on $2^{-\Delta\Delta Ct}$ values from qPCR. An amplicon from the plasmid without the RE recognition site (pT7RNAP) was used as the reference sequence. Results are shown after applying the assay to the *E. coli* I-E Cascade following a TXTL reaction with 3 nM Cascade plasmid for 16 h or 0.25 nM Cascade plasmid for 8 h. Less protection, which can produce a stricter PAM profile, is achieved when using a lower Cascade plasmid concentration or a shorter incubation time (see **Note 8**). A control reaction without the Cascade or crRNA plasmids in the TXTL reaction shows negligible protection. Bars reflect the mean and error bars reflect the standard deviation from the duplicate reactions.

Quantitative PCR (qPCR)

1. Design two primer pairs. One amplifies a 100–250 bp long region containing the PAM library (pr-05, pr-06). The other amplifies a plasmid added to every single reaction but is not digested by your RE (pT7RNAP, pr-07, pr-08) and generates a similar amplicon size.
2. Use a qPCR kit without a reverse-transcription step to amplify the DNA obtained with the PAM assay with the primer pairs from step 1.

- Determine the fold change between digested and undigested samples. Calculate $2^{-\Delta\Delta Ct}$ using the undigested sample as the control sample and the amplicon from the plasmid without RE recognition site (pT7RNAP) as the reference sequence. The fold change shows how much of your targeted plasmid is protected by the CRISPR-Cas systems and not prone to RE digestion. A fold change of 0.01 or lower indicates no binding of the CRISPR-Cas system (**Figure 3B**).

NGS Library Preparation

- Amplify the EtOH precipitated DNA from Subheading “DNA extraction” with a nuclease appropriate for NGS library preparation adding Illumina sequencing primer binding sites on both ends of the amplicons containing the PAM library region (pr-09, pr10) (**Figure 4**).

Figure 4: NGS library preparation. A region of the targeted plasmid is amplified that spans the PAM region (red) and the protospacer region (gray) including the RE recognition site (blue). Primers (pr-09, pr-10) are used that add the Illumina sequencing primer sites (light purple). Flow cell binding sites (dark purple) and the i7 and i5 indices are added in a second PCR (pr-11, pr-12). Directions of Read1 and Read2 generated by NGS are shown.

2. Check the amplicons on an agarose gel.
3. Purify the amplicon with an appropriate method, e.g., use AMPure beads.
4. Add the flow cell binding sequences and unique dual indices to both sides of the amplicon by amplifying the amplicon at the Illumina sequencing primer binding sites with a nuclease appropriate for NGS library preparation (pr-11, pr-12) (**Figure 4**).
5. Check the amplicons on an agarose gel.
6. Purify the amplicon with an appropriate method, e.g., use AMPure beads.
7. Sequence the amplicon with a NovaSeq 6000 Sequencing System with 50 bp paired-end reads.

NGS Data Analysis

Data analysis is done according to Leenay et al. [40]. A detailed protocol can be found there. The analysis starts with raw.fastq files. The following protocol is based on the sequence of **Figure 4** and can be adjusted according to the plasmid encoding the PAM library.

1. List the nucleotides from the randomized region with the following code:
 Read 1:

```
grep '[TCAG][TCAG][TCAG][TCAG][TCAG]AATTCTGGCGAATCCTTTAATTAA'
Sample1.fastq | cut -c 22-26 | sort | uniq -c | sort -nr | less > Sample1List.txt
```

 Read 2:

```
grep 'TTAATTAAGGATTCGCCAGAATT[TCAG][TCAG][TCAG][TCAG][TCAG]'
Sample1.fastq | cut -c 43-47 | sort | uniq -c | sort -nr | less > Sample1List.txt
```
2. Import the .txt list into Microsoft Excel and sort it with the Sort and Filter tool.
3. Calculate PAM enrichment with the following formula:

$$\text{Enrichment} = \frac{\text{total reads non - digested sample}}{\text{total reads digested sample}} \times \frac{\text{reads digested sample}}{\text{reads non - digested sample}}$$

4. Use the calculated PAM enrichments and the PAM sequences to generate Krona Plots by adding them to the KronaExcelTemplate (available at <https://github.com/marbl/Krona/wiki>) and using Category 1 for the nucleotide adjacent to the protospacer (see **Note 14**) (**Figure 5**).
5. The generated Krona Plot can be viewed as a .html file with any web browser. The file can be downloaded and modified (**Figure 6**) (see **Note 15**).

| Enrichment | Category 1 | Category 2 | Category 3 | Other categories | 5' to 3' |
|------------|------------|------------|------------|------------------|----------|
| 1.28074176 | A | A | A | A | AAAAA |
| 2.29633284 | C | A | A | A | AAAAC |
| 2.66738671 | G | A | A | A | AAAAG |

Figure 5: Populating the Krona Excel template to generate the PAM wheel. Positioning of the calculated PAM enrichments and the sorted PAM in the Excel template file are shown. The PAM sequences are depicted in their 5' to 3' direction. To achieve a 5' to 3' order from the outer circle to the inner circle in the PAM wheel, the nt in the -5 position is placed in Category 1, the nt in the -4 position in Category 2, and so on.

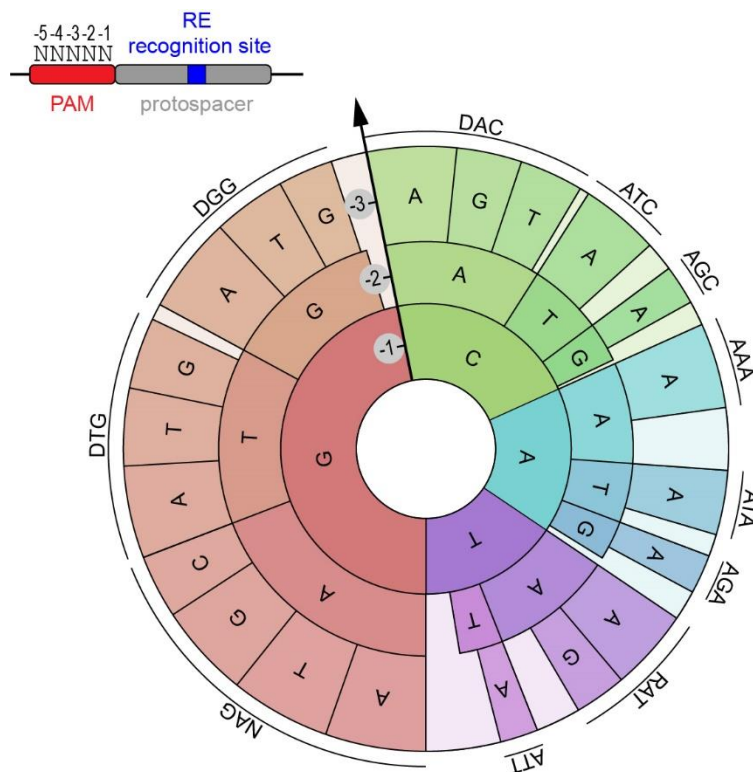

Figure 6: PAM wheel for the PAM determination assay conducted with Cascade from *E. coli*'s Type I-E system. The Krona Plot representing recognized PAMs generated from the example data with 3 nM Cascade and an incubation time of 16 h is shown. Thereby, only three nts are depicted as positions -4 and -5 did not show any nucleotide specificity. The section size of a PAM sequence is proportional to its enrichment during the PAM assay

Data Validation

TXTL can be also used to validate the PAMs that were found in the Krona Plot. A convenient method for this is to target the promoter region of a deGFP encoding plasmid (pGFP-Pacl)

(Figure 7A). Clone each PAM-of-interest upstream of the -35 region of the promoter with the targeted sequence covering parts of the promoter (**Figure 7B**). Recognition of the PAM and thus binding of the Cascade-crRNA complex results in repression of deGFP expression, halting the build-up of fluorescence. Fold changes between a reaction containing a CRISPR array with a non-targeting spacer and a reaction containing a CRISPR array targeting the *degfp*-promoter region indicate the functionality of the chosen PAM.

1. Prepare TXTL reactions on ice (**Table 7**) (see **Note 16**). Always include a background control consisting of TXTL and water only.
2. Carefully vortex the reactions and spin them down shortly.
3. Incubate reactions at 29°C for 4 h (see **Note 9**).
4. Add reporter plasmid (here pGFP-CAAAG, pGFP-CAATG, pGFP-ATAAC, pGFP-GTAAT or pGFP-CTATT) to TXTL reaction (**Table 7**), add water to your background control instead.
5. Carefully vortex and briefly spin down your reactions.
6. Load at least technical duplicates of 5 μ L each in a 96-well plate with V-shaped bottom.
7. Seal the loaded plate with a cover mat to prevent evaporation over time.
8. Measure deGFP fluorescence (Ex 485 nm, Em 528 nm) (see **Note 17**) in a plate reader pre-warmed to 29°C (see **Note 9**). Measure fluorescence every 3 min for up to 16 h.
9. Subtract the values of the background control from your samples for every measured timepoint.
10. Calculate fold-changes by dividing the fluorescence of the nontargeting control by the targeting control. High fold-changes represent highly recognized PAMs, low/no fold-changes represent low/no recognition (**Figure 7C**).

Table 7: Components for the TXTL reporter assay to validate identified PAMs

| Component | Volume (μ L) | Initial concentration (nM) | Final concentration (nM) |
|----------------------------------------------------------------------------------------------------|-------------------|----------------------------|--------------------------|
| TXTL | 9 | - | - |
| <i>E. coli</i> Cascade plasmids (pEcCas8, pEcCse2, pEcCas7, pEcCas5, pEcCas6) (see Note 7) | 0.5 | 12 | 0.5 |
| crRNA plasmid (pEc-crRNA2 or pEc-crRNAnt) | 1 | 12 | 1 |
| Reporter plasmid (pGFP-CAAAG, pGFP-CAATG, pGFP-ATAAC, pGFP-GTAAT or pGFP-CTATT) (added later) | 0.5 | 24 | 1 |
| IPTG | 0.12 | 50,000 | 500 |
| T7RNAP (pT7RNAP) | 0.2 | 12 | 0.2 |
| Water | 0.68 | - | - |

Figure 7: Validation of enriched PAM sequences using a TXTL-based reporter assay. (A) Overview of the reporter assay. Plasmids encode the Cascade proteins (pEcCas8, pEcCse2, pEcCas7, pEcCas5, pEcCas6) as well as a crRNA targeting the deGFP promoter (pEc-crRNA2) or a non-targeting crRNA (pEc-crRNAnt). These components are pre-expressed in TXTL at 29°C for 4 h to allow for ribonucleoprotein complex formation prior to expressing the reporter. Addition of a targeted deGFP reporter plasmid (pGFP-CAAAG, pGFP-CAATG, pGFP-ATAAC, pGFP-GTAAT or pGFP-CTATT) leads to binding of the protospacer by the ribonucleoprotein complex with the targeting crRNA, blocking transcription of the reporter. The rate of binding and the efficiency of transcriptional blocking impacts the accumulation of deGFP and the resulting fluorescence of the TXTL reaction. Under this setup, better-recognized PAMs result in less deGFP accumulation and fluorescence. (B) Sequence of the targeted plasmid. A region within the targeted plasmids containing the PAM (red), the protospacer (gray), the promoter (light red), and beginning of the deGFP coding region (light green) is shown. The PAM sequence is located upstream of the promoter, limiting interference with deGFP expression on its own and can be replaced with any sequence-of-interest. (C) deGFP expression levels and fold changes based on endpoint fluorescence. deGFP fluorescence levels of reactions with a targeting crRNA (T) or a non-targeting crRNA (NT) are shown on the left. The bigger the difference in fluorescence between NT and T, the better the PAM is recognized. Fold changes represent the ratio of deGFP fluorescence for the non-targeting reaction over the targeting reaction. Bars reflect the mean and error bars reflect the standard deviation from the duplicate reactions

Notes

1. Online tools can be used to design the mutagenic primers, e.g., NEBase Changer.
2. A deGFP-expressing plasmid can be used for introduction of the unique RE recognition site for an easy visual control of the functionality of the TXTL reaction and for use in later validation (here pGFP-Pacl). A slightly green reaction mix after the incubation time indicates active protein expression (see **Note 17**).
3. Cloning all Cas proteins on separate plasmids allows for the addition of Cas protein encoding plasmids in a stoichiometric manner, while cloning Cascade proteins as an operon on one plasmid facilitates handling.
4. Plasmids can be exchanged with linear DNA if GamS is added to the TXTL reaction (final concentration 2 μ M) or if χ sites are included in the linear construct to prevent RecBCD-induced DNA degradation [41, 42].
5. If a protein-of-interest is toxic, inducible promoters such as T7 promoter or IPTG-inducible promoters can be used.
6. We recommend preparing a MasterMix with TXTL, water and inducer and/or T7 RNA polymerase plasmid if necessary. We do not recommend including any other component (e.g., PAM library plasmid) into the MasterMix to ensure highest independence between replicates.
7. If Cas proteins are encoded on separate plasmids, prepare a MasterMix combining all Cas-encoding plasmids in one sample. Add every plasmid according to the stoichiometry of the encoded Cas protein. Concentration of all Cas-encoding plasmids should result in an initial concentration of 45 or 12 nM. If Cas proteins are encoded on one plasmid, prepare a stock concentration of 45 or 12 nM.
8. If less Cascade protein production is required, e.g., to only select for strong PAMs, add less plasmids encoding for Cas proteins and/or shorten the incubation time.
9. 29°C is commonly used for TXTL reactions and optimal for deGFP production, although the temperature can be varied between 25 and 42°C [43] and can impact the expression and activity of some Cas nucleases [33].
10. A 1:400 dilution of the TXTL reaction is optimized for the RE Pacl. If other enzymes are used, different dilutions of TXTL can be tested for optimal results.
11. We recommend using EtOH precipitation over column-based purification due to the small amount of plasmid DNA remaining in the reaction and the lower DNA recovery of column-based purification compared to EtOH precipitation.
12. This step can proceed overnight.
13. Always place the tube in the centrifuge in the same orientation (e.g., lid pointing toward the center of the rotor) so you know where your DNA pellet is located.

14. People with programming experience can also use the source code and run it on a local machine (see <https://github.com/marbl/Krona/wiki> for more information).
15. Other visualization methods besides Krona Plots can be used. Examples are sequence logos or motif plots [40, 44, 45].
16. Determination of the optimal Cascade plasmid concentration may be required if overall fluorescence is low.
17. deGFP can be exchanged with other fluorescence reporters.
18. We recommend preparing a MasterMix with TXTL, water, Cascade plasmids, crRNA plasmid and inducer and/or T7 RNA polymerase plasmid if necessary.

Summary

CRISPR-Cas biology and technologies have been largely shaped to-date by the characterization and use of single-effector nucleases. By contrast, multi-subunit effectors dominate natural systems, represent emerging technologies, and were recently associated with RNA-guided DNA transposition. This disconnect stems from the challenge of working with multiple protein subunits *in vitro* and *in vivo*. Here, we apply cell-free transcription-translation (TXTL) systems to radically accelerate the characterization of multi-subunit CRISPR effectors and transposons. Numerous DNA constructs can be combined in one TXTL reaction, yielding defined biomolecular readouts in hours. Using TXTL, we mined phylogenetically diverse I-E effectors, interrogated extensively self-targeting I-C and I-F systems, and elucidated targeting rules for I-B and I-F CRISPR transposons using only DNA-binding components. We further recapitulated DNA transposition in TXTL, which helped reveal a distinct branch of I-B CRISPR transposons. These capabilities will facilitate the study and exploitation of the broad yet underexplored diversity of CRISPR-Cas systems and transposons.

Introduction

CRISPR-Cas systems endow prokaryotes with an adaptive defense against invading elements and possess effector nucleases that have become versatile biomolecular tools (Barrangou and Doudna, 2016; Pickar-Oliver and Gersbach, 2019). These systems are remarkably diverse, with two classes, six types, over 30 subtypes, and a few subtype variants defined to-date (Makarova et al., 2020). The two classes are distinguished based on whether the effector nuclease responsible for CRISPR RNA (crRNA)-directed immune defense comprises a multi-protein complex (class 1) or a single multi-domain protein (class 2). Within these classes, class 2 systems have been the most extensively explored. For example, comprehensive determination of target-flanking protospacer-adjacent motifs (PAMs) (Leenay and Beisel, 2017) has been conducted on more than 100 class 2 effectors spanning at least 15 subtypes (Collias and Beisel, 2021) but only on 10 class 1 effectors spanning 7 subtypes (**Table S1**). Despite this discrepancy, class 1 systems represent over 75% of all CRISPR-Cas systems found in nature, contain phylogenetically diverse proteins possessing unique mechanisms of action (Makarova et al., 2015), and are associated with emerging alternative functions (Li et al., 2021). The associated machinery has also been recently applied as tools in mammalian and plant cells, offering distinct means of achieving gene regulation, genome editing, and variable chromosomal deletions (Cameron et al., 2019; Chen et al., 2020; Dolan et al., 2019; Liu et al., 2018; Morisaka et al., 2019; Osakabe et al., 2020; Pickar-Oliver et al., 2019; Zheng et al., 2020). Finally, a subset of class 1 systems contain Tn7-like transposon genes and were shown to mediate crRNA-directed transposition. These CRISPR-associated transposons

(CASTs) have since been employed in bacteria for the efficient, programmable, and multiplexed insertion of donor DNA exceeding 10 kb (Chen et al., 2021; Klompe et al., 2019; Park et al., 2021; Petassi et al., 2020; Peters et al., 2017; Rybarski et al., 2021; Saito et al., 2021; Strecker et al., 2019; Vo et al., 2021). These examples highlight the potential of further exploring and harnessing class 1 CRISPR-Cas systems and CASTs.

The disconnect between the broad relevance of class 1 systems and the few well-characterized examples can be largely attributed to the challenge of working with multiple protein subunits. Cell-based assays are complicated by the need to encode and optimally express multiple subunits from a minimal number of constructs, whereas *in vitro* assays require intensive purification of multi-subunit complexes – tasks that are far simpler for single-effector nucleases. A promising alternative came with the advent of cell-free transcription-translation (TXTL) systems and their use for rapidly and scalably characterizing CRISPR-Cas systems (Garamella et al., 2016; Jiao et al., 2021; Liao et al., 2019a, 2019b; Marshall et al., 2018; Maxwell et al., 2018; Silverman et al., 2020; Watters et al., 2018). As part of a TXTL reaction, circular or linear DNA constructs are added to the TXTL mix, resulting in the transcription and translation of the encoded products in minutes to hours. In our prior work, we showed that TXTL could functionally express the type I effector complex Cascade (CRISPR-associated complex for antiviral defense) that yielded transcriptional repression of a reporter gene (Marshall et al., 2018). However, all other implementations of TXTL to-date have focused on single-effector nucleases (Khakimzhan et al., 2021; Liao et al., 2019a, 2019b; Wandera et al., 2020; Watters et al., 2018). Here, we leverage TXTL to rapidly characterize diverse type I systems and transposons, allowing ortholog mining, characterization of self-targeting systems, and harnessing of CASTs. The resulting capabilities should accelerate the exploration and exploitation of this broad yet understudied branch of CRISPR biology.

Design – PAM-DETECT: a TXTL-based enrichment assay for PAM determination

One of the defining features of DNA-targeting CRISPR-Cas systems is the PAM (Leenay and Beisel, 2017). This collection of sequences always flanks a crRNA target and allows the effector nuclease to discriminate between self (the associated spacer in the CRISPR array) and non-self (the targeted invader). The associated sequences can vary widely even between close homologs (Collias and Beisel, 2021). Given that prior comprehensive PAM determination assays applied to class 1 systems involved laborious *in vitro* or cell-based assays (**Table S1**), we devised a TXTL-based assay that could elucidate the complete PAM profile recognized by an effector complex but without the need for protein purification or cellular expression (**Figures 1A and 1B; Methods S1**). The assay involves expressing the crRNA and the three to five Cas

proteins to form Cascade, which then binds target DNA. Even though Cascade binding normally recruits the endonuclease Cas3 (Hochstrasser et al., 2014; Huo et al., 2014; Westra et al., 2012; Xiao et al., 2017) to nick and processively degrade the non-target strand of DNA (Gong et al., 2014; Huo et al., 2014; Mulepati and Bailey, 2013; Westra et al., 2012; Xiao et al., 2017, 2018), Cascade strongly binds DNA even without Cas3 (Jackson et al., 2014; Jore et al., 2011; Mulepati et al., 2012; Westra et al., 2012). As part of the TXTL-based assay, Cascade binds target DNA flanked by a library of potential PAM sequences. A restriction enzyme is then introduced that cleaves a sequence within the DNA target. As a result, DNA containing a recognized PAM sequence is protected by the bound Cascade from cleavage, thereby enriching this sequence within the library. Next-generation sequencing (NGS) is then performed to quantify the relative frequency of each PAM sequence before and after restriction digestion. We call this assay PAM-DETECT (PAM DETermination with Enrichment-based Cell-free TXTL). From the addition of the DNA constructs to the isolation of library DNA for NGS, the entire process requires 13-23 h.

Figure 1: PAM-DETECT, a TXTL-based PAM determination assay for multi-protein CRISPR effectors. (A) DNA components added to a TXTL reaction to perform PAM-DETECT. The Cascade genes can be encoded on separate plasmid, as shown here, or as an operon. (B) Steps comprising PAM-DETECT. RE, restriction enzyme. (C) Determination of PAM enrichment by Sanger sequencing.

As part of PAM-DETECT, we devised two parallel checkpoints to assess the extent of library protection and PAM enrichment prior to submitting samples for NGS. For the first checkpoint (**Figure 1C**), quantitative PCR (qPCR) is applied with a digested and undigested library to measure the extent to which the library was protected by Cascade binding. Given that excess

effector can boost the prevalence of less-preferred PAM sequences (Karvelis et al., 2015), the qPCR results can indicate the stringency of the determined PAM sequences. Fortunately, the conditions of PAM-DETECT can be readily tuned by changing the concentration of the added DNA constructs and the time allowed for Cascade expression and DNA binding. For the second checkpoint (**Figure 1D**), the digested and undigested libraries are subjected to Sanger sequencing. Elevated peaks in the digested versus undigested sample reflect enrichment of those bases at that PAM position, providing a preliminary indication of the determined PAM.

Results

PAM-DETECT validated with the canonical type I-E CRISPR-Cas system from *Escherichia coli*

To evaluate PAM-DETECT, we began with Cascade encoded by the type I-E CRISPR-Cas system from *Escherichia coli* (*E. coli*) (**Figure 2A**). As part of its extensive characterization, the effector complex has been subjected to multiple comprehensive PAM determination assays (Caliando and Voigt, 2015; Fineran et al., 2014; Fu et al., 2017; Leenay et al., 2016; Musharova et al., 2019; Xue et al., 2015), establishing a complex landscape principally composed of the canonical PAM sequences AAG, AGG, ATG, and GAG (written 5' to 3') located on the non-target strand immediately upstream of the sequence matching the crRNA guide. We applied PAM-DETECT by encoding the five Cascade genes and a targeting single-spacer CRISPR array on six separate plasmids and combining these plasmids with a 5-base PAM target library harboring a *PacI* restriction site (**Figure 2A**). To explicitly evaluate the impact of excess effector complexes, we tested two different conditions: one with 0.25 nM of Cascade-encoding plasmids and 6-h reaction time for low Cascade expression/binding and another with 3 nM of Cascade-encoding plasmids and 16-h reaction time for high Cascade expression/binding. The qPCR check showed significant DNA protection compared with the control lacking Cascade, with ~2-fold more protection for the high-versus low-Cascade condition (**Figure 2B**). In parallel, the Sanger-sequencing checkpoint showed enrichment of an AAG motif compared with the undigested control, where the motif was more pronounced for the low-Cascade condition (**Figure 2C**). The checkpoints were in line with the protection of DNA sequences related to the known PAM, with heightened protection for the high-Cascade condition.

Proceeding to NGS, we visualized the results as a PAM wheel to capture both individual sequences and enrichment scores (Leenay et al., 2016; **Figure 2D**). The PAM wheel for the low-Cascade condition captured the four known canonical PAMs as well as other well-recognized PAM sequences (e.g., TAG and AAC). The PAM wheel for the high-Cascade condition included these PAM sequences as well as other PAM sequences that were less

enriched (e.g., AAA and AAT) or negligibly enriched (e.g., CAG and ATT) for the low-Cascade condition (**Figure 2D**). The differences in PAM profiles demonstrate how PAM-DETECT can be readily tuned by varying plasmid concentration and reaction time.

Figure 2: Validation of PAM-DETECT with the I-E CRISPR-Cas system from *E. coli*. (A) The type I-E CRISPR-Cas systems from *E. coli*. The genes encoding the Cascade complex are in the light orange box, and the genes encoding the acquisition proteins are in the gray box. Right: 5N library of potential PAM sequences used with PAM-DETECT. (B) Extent of PAM library protection under conditions resulting in low or high Cascade based on qPCR. Library protection compares the library with and without RE digestion. (C) Effect of low or high levels of Cascade based on Sanger sequencing. Over-representation of T and C at the -5 and -4 position, respectively, can be explained by the library generation, as TCAAG represented one of the most prevalent sequences in the library. (D) Nucleotide-enrichment plots and PAM wheels based on conducting PAM-DETECT with low or high levels of Cascade. Individual sequences comprising at least 2% of the PAM wheel are shown. Results represent the average of duplicate independent experiments. The size of the arc for an individual sequence corresponds to its relative enrichment within the library. (E) Overview of the TXTL-based PAM validation assay. PAM sequences are tested by Cascade binding target R flanked by the tested PAM. Because target R overlaps the promoter driving expression of deGFP, target binding blocks deGFP expression. Target R is distinct from the restriction site-containing target used with PAM-DETECT. (F) Correlation between PAM enrichment from PAM-DETECT and gene repression in TXTL. Enrichment values represent the mean of duplicate PAM-DETECT assays, whereas fold-reduction values represent the mean of triplicate TXTL assays. Fold-reduction was calculated based on a non-targeting crRNA control. (G) TXTL validation of PAM sequences identified by PAM-DETECT but not previously by PAM-SCANR. CAAAG serves as a positive control. The AACCG self PAM matches the 3' end of the repeat and is the reference for statistical analyses.

Error bars in (B) and (G) indicate the mean and standard deviation of triplicate independent experiments. ***p < 0.001, **p < 0.01, *p < 0.05, and ns: p > 0.05.

To validate the results, we applied TXTL to silence plasmid-based expression of deGFP, a truncated version of eGFP that is more efficiently translated in cell-free systems (Shin and Noireaux, 2010, 2012). By targeting a distinct target sequence overlapping the deGFP promoter (**Figure 2E**; **Table S2**), the PAM sequence could be altered without affecting the promoter sequence. For representative PAM sequences, the fold-repression of deGFP production versus a non-targeting control strongly correlated with the enrichment score of each sequence in PAM-DETECT for the low-Cascade condition ($R^2 = 0.99$) (**Figure 2F**). Applying the same assay to PAM sequences enriched under the high-Cascade condition but not detected with our previous PAM-SCANR method (Leenay et al., 2016), we measured modest but significant deGFP repression (**Figure 2G**). These validation experiments show that PAM-DETECT can produce comprehensive and quantitative PAM profiles.

Distinct PAM profiles pervade I-E CRISPR-Cas systems

Nuclease mining has been highly successful for identifying single-effector nucleases such as Cas9 with a wide spectrum of PAMs (Gasiunas et al., 2020; Zetsche et al., 2020) and thus could be highly valuable when applied to class 1 systems. Focusing again on the I-E subtype, we began by identifying diverse Cas8e proteins responsible for PAM recognition within Cascade (van Erp et al., 2015; Hayes et al., 2016) from mesophilic bacterial strains. We divided the identified set of 213 Cas8e proteins in groups according to the amino-acid sequence of the highly variable L1 loop within the N-terminal domain (**Table S3**) reported to stabilize Cas8e-PAM interactions (Tay et al., 2015; Xiao et al., 2017). We selected 11 representative I-E systems reflecting some of the most abundant L1 motifs (**Figures 3A** and **S1**). The resulting Cascade complexes could be readily characterized with PAM-DETECT in parallel despite involving 55 Cascade genes and 11 single-spacer arrays, each in separate plasmids. We selected the high-Cascade conditions (3-nM plasmids and 16-h reaction time) given the uncertainty about how well a given system would be functionally expressed in TXTL. All but one system yielded significant enrichment of the PAM library, compared with a non-digested control (**Figure S1A**), allowing us to determine a large number of PAM profiles.

PAM-DETECT revealed a broad range of recognized PAMs (**Figures 3A** and **S1B**). The PAM profile most distinct from that associated with the *E. coli* Cascade was recognized by Cascade from *Streptococcus thermophilus* DGCC 7710 (Sth). This profile comprised any sequence with an A or T at the -1 position as well as (S = G and C) and ATS, which included the few PAM sequences previously confirmed to bind purified Cascade *in vitro* (Sinkunas et al., 2013). Most remaining systems generally recognized AAG as a dominant PAM sequence, although there were notable deviations and additions. For example, one system from *Azotobacter chroococcum* NCIMB 8003 (Ac2) principally recognized AA, whereas another

system from *Paracoccus* sp. J4 (Ps) preferentially recognized AAC. Interestingly, Ac2 and a separate system from *Azotobacter chroococcum* NCIMB 8003 (Ac3) are present in the same bacterium, suggesting that their partially overlapping PAM profiles could confer redundancy in immune defense as reported for co-occurring type I and type III systems (Silas et al., 2017). The distinct PAM profiles that gave measurable activity in the deGFP silencing assay in TXTL confirmed the trends observed with the PAM wheels (Figure 3B). Given that type I-E systems represent one of the most abundant CRISPR-Cas subtypes in nature (Makarova et al., 2015), our initial characterization suggests that a far greater diversity of recognized PAM profiles likely exists.

Figure 3: Harnessing the functional diversity of I-E CRISPR-Cas systems. (A) Nucleotide enrichment plots and PAM wheels for selected I-E systems subjected to PAM-DETECT. Ac1 (Figure S1), Ac2, and Ac3 are present in the same bacterium. Individual sequences comprising at least 2% of the PAM wheel are shown. Plots and PAM wheels are averages of duplicate independent experiments. (B) Comparison of PAM recognition between systems. Recognition was determined by assessing the repression of a deGFP reporter in TXTL. Values represent the mean of three TXTL experiments. Fold-reduction values that are not significantly different from that of the non-targeting crRNA control ($p > 0.05$) are shown as white squares. The PAM sequence showing the highest fold reduction for each system was set to 100%. AACCG matches the 3' end of the repeat for most of the systems.

Extensive self-targeting I-C and I-F1 CRISPR-Cas systems in *Xanthomonas albilineans* are functionally encoded

Beyond nuclease mining, PAM-DETECT can be further applied to interrogate systems that deviate from traditional immune defense. Prominent examples are self-targeting CRISPR-Cas systems that encode crRNAs targeting chromosomal locations (Wimmer and Beisel, 2019). Although self-targeting is considered inherently incompatible with a functional CRISPR-Cas system (Gomaa et al., 2014; Stern et al., 2010; Vercoe et al., 2013), accumulating examples provide important counterpoints where the systems tolerate or even utilize self-targeting crRNAs (Li et al., 2021; Marino et al., 2018; Rauch et al., 2017; Watters et al., 2018; Yin et al., 2019). PAM-DETECT and TXTL therefore could accelerate the characterization of these unique systems.

We specifically focused on two extensively self-targeting CRISPR-Cas systems within the plant pathogen *Xanthomonas albilineans* CFBP7063. This bacterium encodes two CRISPR-Cas systems (I-C and I-F1), each harboring the full cohort of *cas* genes (**Figure 4A**). Furthermore, of the 64 spacers present across the six CRISPR arrays, 24 (38%) at least partially match sites in the chromosome or one plasmid (**Table S4; Figure S2A**) with a common set of flanking PAMs (**Figure 4B**). The ensuing questions are whether they could lead to autoimmunity through their self-targeting spacers.

We first performed PAM-DETECT using Cascade from both CRISPR-Cas systems to assess whether both are functionally encoded and what PAM profiles they recognize (**Figure 4C**). Either Cascade protected a small portion of the DNA library (~2% for I-C, ~6% for I-F1) from restriction digestion (**Figure S2B**), indicating functional expression of all Cascade subunits. PAM-DETECT further revealed PAM profiles that overlapped – but were not identical to – the I-C and I-F1 systems with even a moderately mapped PAM profile (Almendros et al., 2012; Leenay et al., 2016; Rao et al., 2017; Rollins et al., 2015; Tuminauskaite et al., 2020; Zheng et al., 2019). In particular, the I-C system from *X. albilineans* recognizes TTC followed by TTT and CTC, whereas the characterized I-C system from *Bacillus halodurans* recognizes TTC followed by CTC and then TCC (Leenay et al., 2016) and the I-C system from *Legionella pneumophila* recognizes TTC followed by TTT and CTT (Rao et al., 2017). Separately, the I-F1 system from *X. albilineans* recognizes CC as the strongest PAM similar to other I-F systems (Almendros et al., 2012; Rollins et al., 2015; Tuminauskaite et al., 2020; Zheng et al., 2019), although the *X. albilineans* system also can recognize a G and T but not an A at the -2 position and, in this case, could tolerate a CC PAM shifted upstream by one nucleotide. The recognized PAMs of both I-C and I-F1 systems further overlapped with the PAM sequences flanking the self-targets for 87% of the I-C self-targets (TTC, TTT, and CTC) and all I-F1 self-targets (CC

and CCT) (**Figures 4B** and **4C**). Testing individual PAMs in TXTL using gene repression with Cascade confirmed that the I-C system could recognize not only TTC but also TTT and CTC (**Figure 4D**). Similarly, the I-F1 system could recognize the CC PAM associated with almost all self-targets. PAM-DETECT thus can be implemented beyond I-E systems, and it indicated that the interrogated I-C and I-F1 systems in *X. albilineans* are capable of binding the vast majority of self-targeting sites in the genome.

Figure 4: Interrogating extensive self-targeting for two Type I CRISPR-Cas systems in *X. albilineans*. (A) Overview of the I-C and I-F1 CRISPR-Cas systems and self-targeting spacers. The genes encoding the Cascade complex are in the light blue box (I-C) or the light orange box (I-F1), and the genes encoding the acquisition proteins are in the gray box. (B) Distribution of PAMs associated with the self-targets. See **Figure S2** for the self-target location and **Table S4** for the self-target sequences. (C) Nucleotide-enrichment plots and PAM wheels based on conducting PAM-DETECT. Individual sequences comprising at least 2% of the PAM wheel are shown. Plots and PAM wheels are averages of duplicate independent experiments. (D) Validation of PAMs associated with self-targets in TXTL. See **Figure 2E** for details. The self PAMs GAAAC (I-C) and AGAAA (I-F1) are references for statistical analyses. (E) Assessing DNA binding by Cascade and DNA degradation by Cas3 in TXTL. See **Figure 2E** for details about target R. Targeting far upstream of the promoter (target D) can reduce deGFP levels only through degradation of the plasmid. The non-targeting crRNA control is the reference for statistical analyses. Errors bars in (D) and (E) indicate the mean and standard deviation of triplicate independent experiments. *** $p < 0.001$, ** $p < 0.01$, * $p < 0.05$, and ns: $p > 0.05$.

If the Cas3 endonuclease for either system is functionally encoded and expressed, then recognition of these self-targeting sites should prove lethal to this bacterium. We therefore reconfigured the TXTL assay to evaluate the extent to which the I-C or I-F1 Cas3 could elicit DNA degradation (**Figure 4E**). The DNA target was placed in the backbone of the deGFP reporter ~200 bps upstream of the deGFP promoter (target D) flanked by a TTC (I-C) or CC (I-F1) PAM. Under this setup, loss of deGFP fluorescence would occur only if the backbone is nicked or cleaved, leading to DNA degradation by RecBCD (Marshall et al., 2018). For both CRISPR-Cas systems, this target site location resulted in targeted deGFP silencing following expression of Cascade and Cas3 but not Cascade alone (**Figure 4E**). The extent of deGFP silencing was less than that when targeting the deGFP promoter (target R), which can be explained by silencing through target R requiring Cascade binding versus silencing through target D requiring Cascade binding, Cas3 cleavage, and RecBCD degradation. Similar extents of deGFP silencing through Cas3 were observed when testing two native spacer:self-target pairs for each system (**Figure S2C**). We conclude that Cas3 is functionally encoded and would lead to lethal self-targeting unless Cascade or Cas3 is fully silenced in this bacterium, or another mechanism is in place to inhibit Cascade and/or Cas3 activity.

The I-F CRISPR transposon from *Vibrio cholera* recognizes an extremely flexible PAM profile

The demonstrated applicability of PAM-DETECT for diverse type I CRISPR-Cas systems created a unique opportunity: applying the same assay to CASTs. Of the three known CAST types (I-B, I-F, and V-K), two (I-B and I-F) rely on Cascade for DNA target recognition (Klompe et al., 2019; Saito et al., 2021). Recognition then leads to integration of the transposon DNA at a defined distance downstream of the target. Characterization of these systems to-date has relied on encoding a crRNA, all CRISPR and transposon components, and donor DNA flanked by the transposon ends in bacteria to achieve targeted transposition. However, the reliance of I-B and I-F CASTs on Cascade offers an opportunity to express only these CAST components as part of PAM-DETECT to elucidate rules for DNA target recognition.

We began with the I-F CAST from *Vibrio cholerae* (*V. cholerae*) (VcCAST) that exhibited robust DNA integration in *E. coli* and has been used for multiple applications in bacteria (Klompe et al., 2019; Vo et al., 2021; **Figure 5A**). Prior screening of individual potential PAM sequences via transposition in *E. coli* established a general preference for a C at the -2 position (Klompe et al., 2019), although a comprehensive PAM remained to be determined. We applied PAM-DETECT by expressing the three Cascade genes along with *tniQ* responsible for recruiting the other three transposon proteins (TnsA, TnsB, and TnsC), as the role of TniQ in DNA target recognition remained to be established (Klompe et al., 2019; Petassi et al., 2020;

Vo et al., 2021). High-Cascade conditions (3-nM plasmids and 16-h reaction time) protected 57% of the DNA, leading us to also perform PAM-DETECT with low-Cascade conditions (0.25-nM plasmids and 6-h reaction time) that exhibited 25% DNA protection (**Figure S3A**). The resulting PAM profile was remarkably flexible, with a preference for a C and bias against an A at the -2 position (**Figures 5B** and **S3B**). We further noticed that recognition of a G or T at the -2 position could be enhanced with a C at the -1 position or and A at the -3 position. Separately, an A at the -2 position could be rescued with a C at the -3 position (**Figures 5B** and **S3B**). Recognition was maintained even in the absence of *tniQ* (**Figures 5C** and **S3C**). The results from PAM-DETECT therefore suggest that Cascade from the I-F VcCAST recognizes a remarkably flexible PAM profile with preferences extending beyond a simple consensus sequence.

Figure 5: Interrogating the PAM profile of VcCAST. (A) Overview of VcCAST and its mechanism of transposition. (B) Nucleotide-enrichment plot and PAM wheel based on conducting PAM-DETECT with Cascade and TniQ. Individual sequences comprising at least 1% of the PAM wheel are shown. The plot and PAM wheel are averages of duplicate independent experiments. (C) Validation of PAMs in TXTL. See **Figure 2E** for details. The ATAAC self PAM is the reference for statistical analyses. (D) Individual measurements of endpoint deGFP levels in TXTL. Triplicate values are shown for selected PAMs with a targeting (T) or non-targeting (NT) crRNA. See (C) for details. (E) Validation of PAM recognition for DNA transposition in *E. coli*. Donor DNA is inserted within the *lacZ* gene, preventing the formation of blue colonies on IPTG and X-gal. The targets for the CAA and AAA PAMs are shifted by one nucleotide. See **Figure S3**.

Error bars in (C–E) indicate the mean and standard deviation of triplicate independent experiments. *** $p < 0.001$, ** $p < 0.01$, * $p < 0.05$, and ns: $p > 0.05$.

To evaluate the PAM profile output by PAM-DETECT, we first employed our TXTL-based deGFP silencing assay (**Figure 5C**). Cascade most strongly recognized PAM sequences with C at the -2 position, with the greatest performance for CC. Deviating from CC reduced but did not eliminate measurable silencing as long as A was not present at the -2 and -3 positions.

Interestingly, whereas AAA and AAT yielded no measurable deGFP silencing, replacing A with C at the -3 position restored measurable silencing, albeit with low activity (**Figure 5D**). To assess how these small but measurable differences impact DNA transposition, we employed the previously described transposition system *in E. coli* (Klompe et al., 2019) conducted at 30°C for higher integration efficiency (Vo et al., 2021). Using this experimental setup, we found that CAA but not AAA yielded robust DNA transposition despite the targets being separated by only one base (**Figures 5E, S3D, and S3E**). Furthermore, the measured transposition efficiency was similar for CAA and CC. Therefore, even low levels of gene silencing with Cascade in TXTL can translate into efficient transposition in *E. coli*.

The I-B2 CRISPR transposon from *Rippkaea orientalis* recognizes a less flexible PAM profile

We next turned to I-B CASTs. Two examples of I-B CASTs were experimentally characterized recently, revealing that a second TniQ (renamed TnsD) drives DNA transposition at conserved sites flanking tRNAs or *glmS* independently of Cascade or a crRNA (Saito et al., 2021). Type I-B CASTs were further split into two subtypes (I-B1 and I-B2) based on TnsA and TnsB proteins being fused or separate, the general genetic organization of the CAST locus, and crRNA-independent insertion flanking tRNAs or *glmS*.

While exploring examples within the I-B CASTs, we noticed a further division within the I-B2 subtype typified by *tnsD* flanking the Cascade genes rather than the other transposon genes (**Figure 6A**). This organization more closely parallels that of I-B1 CASTs (Saito et al., 2021) but still possesses the *tnsAB* fusion and the presence of tRNAs flanking the CASTs indicative of I-B2 CASTs. The division of the I-B2 CASTs in two clades, denoted hereafter as I-B2.1 and I-B2.2, was further supported by the higher shared similarity of the TnsAB, TnsC, TnsD and TniQ proteins from systems that belong to each clade (**Figures 6A and S4A**). The Cascade protein sequences were similar across all I-B CASTs. We chose the I-B2.2 CAST from *Rippkaea orientalis* (*R. orientalis*) (RoCAST) as a representative example to characterize.

PAM-DETECT yielded a PAM profile for the RoCAST Cascade dominated by ATG (**Figures 6B, S4B, and S4C**), matching the PAM recognized by the one previously characterized I-B2.1 CAST from *Peltigera membranacea cyanobiont 210A* (PmcCAST) (Saito et al., 2021). This match was expected given the high similarity (65%-81%) between the protein components forming PmcCAST and RoCAST Cascade. However, single-base perturbations to ATG (e.g., GTG) could be recognized by the RoCAST even under low-Cascade conditions. The TXTL-based deGFP silencing assay confirmed recognition of ATG as well as the single-base perturbations (**Figure 6C**). We further showed that PAM-DETECT can be applied to the

previously characterized I-B1 CRISPR transposon from *Anabaena variabilis* ATCC 29413 (AvCAST) (Saito et al., 2021; **Figures S5A and S5B**).

Figure 6: Interrogating PAM requirements of the *Rippkaea orientalis* I-B2.2 CRISPR transposon. (A) Overview of I-B2.1 and I-B2.2 CRISPR transposons. The two are divided based in the gene organization within each transposon. Phylogenetic trees are shown for the transposon genes. The PmcCAST from the I-B2.1 branch was previously characterized (Saito et al., 2021). (B) Nucleotide-enrichment plot and PAM wheel based on conducting PAM-DETECT with Cascade from RoCAST. Individual sequences comprising at least 2% of the PAM wheel are shown. The plot and PAM wheel are averages of duplicate independent experiments. (C) Validation of PAMs in TXTL. See **Figure 2E** for details. The CTCAA self PAM is the reference for statistical analyses.

Error bars in (C) indicate the mean and standard deviation of triplicate independent experiments. ***p < 0.001, **p < 0.01, *p < 0.05, and ns: p > 0.05.

DNA transposition by CRISPR transposons can be recapitulated in TXTL

An ensuing question is how insights into PAM recognition translate into DNA transposition. As *in vitro* or cell-based assays are slow and laborious, we instead sought to recapitulate transposition in TXTL (**Figure 7A**). We began with the VcCAST. Combining DNA constructs encoding a targeting single-spacer array, three Cascade genes, four transposon genes, donor DNA flanked by the transposon ends, and a target construct resulted in measurable DNA transposition in both orientations by PCR (**Figure S6A**), even though the transposition

efficiency in TXTL was too low to be effectively quantified by qPCR (**Table S5**). Sanger sequencing of the PCR products revealed the core transposon ends as well as the distance between the target site and insertion site that aligned with prior work (**Figure S6A**). We were also able to reconstitute transposition in TXTL for the I-B1 AvCAST (**Figure S5C**). TXTL thus can be used to recapitulate DNA transposition by CASTs, allowing elucidation of the transposon ends and insertion sites.

DNA transposition by CRISPR transposons can be recapitulated in TXTL

An ensuing question is how insights into PAM recognition translate into DNA transposition. As *in vitro* or cell-based assays are slow and laborious, we instead sought to recapitulate transposition in TXTL (**Figure 7A**). We began with the VcCAST. Combining DNA constructs encoding a targeting single-spacer array, three Cascade genes, four transposon genes, donor DNA flanked by the transposon ends, and a target construct resulted in measurable DNA transposition in both orientations by PCR (**Figure S6A**), even though the transposition efficiency in TXTL was too low to be effectively quantified by qPCR (**Table S5**). Sanger sequencing of the PCR products revealed the core transposon ends as well as the distance between the target site and insertion site that aligned with prior work (**Figure S6A**). We were also able to reconstitute transposition in TXTL for the I-B1 AvCAST (**Figure S5C**). TXTL thus can be used to recapitulate DNA transposition by CASTs, allowing elucidation of the transposon ends and insertion sites.

DNA transposition in TXTL with the *Rippkaea orientalis* CAST establishes a distinct branch within I-B2 CRISPR transposons

We next evaluated DNA transposition in TXTL with the I-B2.2 RoCAST (**Figure 7B**). Because the ends of this transposon were unclear, we constructed a donor DNA construct flanked by two 250-bp sequences predicted to contain the right and left RoCAST ends. We combined the donor DNA and target DNA flanked by an ATG PAM with constructs encoding the I-B2.2 Cascade genes, transposase genes, and a single-spacer CRISPR array. The TXTL reactions resulted in measurable crRNA-directed transposition in both orientations by PCR (**Figure 7C**). Sanger sequencing of the PCR products revealed the core transposon ends along with five bases that are duplicated as part of transposition (**Figure 7B**), similar to other CASTs (Klompe et al., 2019).

Figure 7: Investigating transposition of RoCAST in TXTL and in *E. coli*. (A) Overview of the TXTL-based transposition assay. (B) CRISPR-dependent transposition and determination of transposon ends and insertion distance using the TXTL-based transposition assay with RoCAST. PCR products are specific to the left-right orientation. (C) CRISPR-dependent transposition in TXTL. PCR products span the crRNA target site and the beginning of the cargo for both orientations of transposon insertion. (D) CRISPR-independent transposition in TXTL. PCR products span the end of the *tRNA-Leu* gene and the beginning of the cargo for both orientations of transposon insertion. (E) CRISPR-dependent transposition in *E. coli*. PCR products span the crRNA target site and the beginning of the cargo (left-right orientation). (F) CRISPR-independent transposition in *E. coli*. PCR products span the TnsD target site and the beginning of the cargo (left-right orientation). (G and H) Assessment of insertion distances for CRISPR-dependent transposition in TXTL and in *E. coli*. The constructs lacking *tnsD* (G) or *tniQ* (H) were used. Transposition was determined by NGS of the PCR product spanning the crRNA target site and the beginning of the cargo (left-right orientation) (G) or spanning the end of the *tRNA-Leu* gene and the beginning of the cargo (left-right orientation) (H). All gel images are representative of at least duplicate independent experiments.

Recent work revealed that I-B CASTs possess two distinct modes of transposition: CRISPR-dependent transposition through TniQ and DNA targeting by Cascade and CRISPR-independent transposition through TnsD (Saito et al., 2021). For CRISPR-dependent transposition, TXTL reactions yielded a more pronounced PCR product when including rather

than excluding TniQ, although modest but detectable crRNA-dependent transposition was detected even in the absence of TniQ and TnsD (**Figures 7B, 7C and S6B**). By contrast, TniQ was reported to be required for crRNA-dependent transposition by the I-B1 AvCAST (**Figure S5C**) and the I-B2.1 PmcCAST (Saito et al., 2021). For CRISPR-independent transposition, we swapped the crRNA target for the *tRNA-Leu* gene naturally flanking RoCAST in the *R. orientalis* genome. CRISPR-independent transposition was detected in both orientations (**Figure 7D**). Transposition required TnsAB, TnsC, and TnsD, whereas removing TnsD or replacing it with TniQ eliminated transposition.

We finally asked how the properties of RoCAST observed in TXTL translate *in vivo* (**Figures 7E and 7F**). For CRISPR-dependent transposition, we targeted the *lacZ* gene in the *E. coli* genome at a site flanked by an ATG PAM. Over-expressing Cascade proved to be cytotoxic, reflecting challenges to characterizing CASTs *in vivo*, although the cytotoxicity could be relieved with minimal induction of Cascade expression. In line with the TXTL results, CRISPR-dependent transposition was measurable by PCR in *E. coli* strains expressing the Cascade, TnsAB, TnsC and TniQ proteins, albeit only for the left-to-right insertion orientation (**Figure 7E**). Removing TnsD boosted this mode of transposition (**Figure 7E**). Somewhat paralleling the TXTL results, less efficient transposition was measurable by PCR in the absence of TniQ but not both TniQ and TnsD (**Figures 7E and S6C**). For CRISPR-independent transposition, we targeted a vector carrying the terminal region of the *tRNA-Leu* gene from the *R. orientalis* genome. Matching the TXTL results, TnsAB, TnsC, and TnsD proteins were necessary for transposition (**Figure 7F**).

To compare the insertion distances between the target and the inserted donor DNA in TXTL and in *E. coli*, the PCR products were subjected to NGS. For CRISPR-dependent transposition, transposition in TXTL consistently occurred 78 bps downstream of the PAM, while transposition in *E. coli* principally occurred within a window of 83-89 bps downstream of the PAM (**Figure 7G**). The difference may be attributed to the use of different target sites and insertion contexts as was previously reported for the I-B1 AvCAST (Saito et al., 2021). For CRISPR-independent transposition, transposition in TXTL and in *E. coli* both occurred 31 bps downstream of the *tRNA-Leu* gene (**Figure 7H**). The insertion distances for both modes of transposition are comparable to the insertion windows identified for the other characterized I-B2 system (Saito et al., 2021). Overall, these findings demonstrate that insights from TXTL-based transposition translate into *in vivo* settings.

Discussion

PAM-DETECT offers important advantages over current cell-based and *in vitro*-based methods that should accelerate characterization of class 1 CRISPR-Cas systems and

transposons. As one advantage, PAM-DETECT can be completed in under 1 day when starting from purified DNA constructs and ending with amplicons for NGS. By contrast, cell-based methods require DNA transformation, culturing, growth, and in some cases screening methods that require access to specialized instruments (e.g., fluorescence-activated cell sorting for PAM-SCANR; Leenay et al., 2016) that can require days to weeks. *In vitro* assays can also require more time and extensive optimization irrelevant to TXTL, such as combining the constructs into a small set of compatible plasmids with appropriate expression, purifying components, and tackling issues of toxicity. As a second advantage, the ability to conduct reactions in a few microliters allows PAM-DETECT to be readily scaled, facilitating the parallel interrogation of multiple systems under different reaction conditions. Given these advantages, TXTL-based characterization of class 1 systems could become a standard means to explore these abundant and diverse systems.

We further leveraged TXTL to accelerate the validation and extension of our results from PAM-DETECT. We frequently employed a deGFP repression assay in which target binding by Cascade blocks deGFP expression. One potential limitation is that binding may not correspond to DNA degradation through Cas3, as was reported to some degree for DNA binding and degradation by the I-E system (Xue et al., 2015). However, as part of characterizing the self-targeting CRISPR-Cas systems in *X. albilineans*, we showed that the repression assay could be readily modified to specifically assess DNA degradation by Cas3. Finally, we showed that DNA transposition by CASTs could be fully recapitulated in TXTL. We were able to recapitulate CRISPR-dependent and CRISPR-independent transposition by I-B and I-F CASTs, suggesting that transposition could be recapitulated for V-K CASTs in TXTL as well (Saito et al., 2021; Strecker et al., 2019). With these additional assays in place, TXTL can be applied well beyond PAM determination.

One major application we pursued was mining the natural diversity of I-E CRISPR-Cas systems. Using PAM-DETECT, we evaluated 11 different systems representing diverse sequences within the variable L1 loop of the Cas8e protein. The identified PAMs deviated from those associated with *E. coli*'s I-E system, suggesting that a far broader range of PAMs could be revealed by further interrogating the diversity of these systems. Whether the diversity parallels that observed for Cas9 nucleases remains to be seen and could reflect the distinct forces that shaped the evolution of each system type (Gasiunas et al., 2020). A similar approach could be particularly powerful for mining I-C and I-Fv Cascade complexes that require the fewest number of canonical Cas proteins (Hochstrasser et al., 2016; Pausch et al., 2017). Complexes could be mined exhibiting not only unique PAM preferences but also smaller proteins, altered temperature ranges, or enhanced binding and cleavage activities. Given the proliferation of engineered single effectors with altered PAM recognition (Collias and Beisel,

2021), TXTL could be applied to characterize any similarly engineered variants of type I systems.

Beyond mining orthologs within a CRISPR-Cas subtype, PAM-DETECT offered a powerful means to interrogate CRISPR-Cas systems with potentially unique properties. We specifically focused on a I-C system and a I-F1 system present in *X. albilineans* that encode a large repertoire of self-targeting spacers. Although genetic deactivation of the CRISPR machinery is thought to be a common means of resolving otherwise lethal self-targeting (Stern et al., 2010), we showed that Cascade and Cas3 were functionally encoded and could recognize PAMs flanking the vast majority of self-targets. These findings instead suggest that the expression or activity of the CRISPR machinery is inhibited, preventing lethal self-targeting. We speculate that anti-CRISPR proteins are responsible for the lack of autoimmunity, as VirSorter (Roux et al., 2015) predicts three prophage regions in the genome of *X. albilineans* (**Figure S2A**) and anti-CRISPR proteins (Acrs) are known to often be located in such regions (Davidson et al., 2020). Future work could interrogate what prevents not only these systems from lethal self-targeting not only in *X. albilineans* but also CRISPR-Cas systems with self-targeting spacers in many other organisms. This work could reveal additional classes of Acrs as well as instances of CRISPR-Cas systems performing functions extending beyond adaptive immunity.

As a final example, we applied TXTL to characterize a distinct branch of I-B2 CASTs. When exploring I-B2 CASTs, we noticed a clear division in the genetic organization of these CASTs that paralleled phylogenetic trees for the transposon genes. We found that CRISPR-dependent transposition could occur in TXTL in the absence of TniQ for one branch (I-B2.2), contrasting with the essential role of TniQ described for the other branch (I-B2.1) and subtype (I-B1) (Saito et al., 2021). The type V-K CAST from *Scytonema hofmanni* (ShCAST) was similarly shown to transpose *in vitro* in the absence of TniQ (Strecker et al., 2019), whereas a recent structural study showed that ShTniQ takes part in the formation of the ShCAST transposition complex but is not required for the complex's catalytic function (Querques et al., 2021). Regardless of its biological relevance, TniQ-independent transposition likely reflects distinct biomolecular mechanisms and interactions for this branch of I-B CASTs that further support some division in categorization. As only a small number of CASTs have been characterized to-date, further exploring these unique mobile genetic elements could reveal additional properties and provide CASTs for further technological development and application.

Limitations of the study

Although PAM-DETECT offers numerous advantages over existing PAM determination assays, it comes with some limitations. First, PAM-DETECT is best suited to systems from

mesophilic organisms because the activity of our TXTL system is restricted to 25°C-42°C (Sun et al., 2013), although the DNA-binding and restriction steps could be conducted at elevated temperatures. Second, no simple and rapid means exist to quantify protein production and complex formation in TXTL, which would help differentiate between poor expression and poor binding activity. Third, PAM-DETECT is less suited to probe PAM dependencies for imperfect targets, where bound Cascade would be more likely to dissociate and allow cleavage by the restriction enzyme. Finally, when applying TXTL to characterize DNA transposition by CASTs, we identified some discrepancies between our TXTL results and our *in vivo* results, including the transposition efficiency and the necessity of TniQ for RoCAST.

Method details

Plasmid construction

Standard cloning methods Gibson Assembly, Site Directed Mutagenesis (SDM) and Golden Gate were used to clone plasmids used in TXTL experiments. pPAM_library containing a PAM library with five randomized nucleotides was generated by SDM on p70a-deGFP_Pacl with primers FW531 and FW532 (**Table S6**). Single-spacer CRISPR arrays were generated either with Golden Gate adding spacer sequences in a plasmid containing two repeat sequences interspaced by two Bael or BbsI restriction sites or by SDM on pEc_gRNA1, pEc_gRNA2 or pEc_gRNAnt to change the repeat sequences to match the tested CRISPR systems. Plasmids harboring different PAM sequences for PAM validation assays were generated by SDM on p70a-deGFP_Pacl. To generate plasmids encoding *X. albilineans* type I-C and type I-F1 Cas proteins, genomic DNA isolated from *Xanthomonas albilineans* CFBP7063 was PCR amplified using Q5 Hot Start High-Fidelity 2X Master Mix (NEB) and cloned into pET28a using Gibson

Assembly. All other plasmids were generated with Gibson Assembly or SDM (**Table S6**). All constructed plasmids were verified with Sanger sequencing.

For the VcCAST *in vivo* transposition experiments we cloned into the previously described pSL0284 vector (Klompe et al., 2019) two spacers targeting the *lacZ* gene of the *E. coli* BL21 (DE3) genome, yielding the pQCas_CAA and pQCas_AAA vectors. The protospacer targeted by the former vector has a 5' CAA PAM, whereas the protospacer targeted by the latter vector has a 5' AAA PAM.

For the RoCAST *in vivo* transposition experiments, genes encoding the *Rippkaea orientalis* *tnsAB*, *tnsC*, *tnsD* and *tniQ* were synthesized (Twist Bioscience) and cloned in the pET24a vector in various combinations, resulting in the construction of the pRoTnsABC, pRoTnsABCD, pRoTnsABCQ, pRoTnsABCDQ vectors (**Table S6**). The *Rippkaea orientalis* Cascade operon (*cas6*, *cas8*, *cas7*, *cas5*) was synthesized (Twist Bioscience) and cloned into the pCDFDuet-1 vector together with a *gfp* gene flanked by two *BsaI* restriction sites and the corresponding CRISPR direct repeats. Into the resulting pRoCascade_gfp vector we cloned a spacer targeting the *lacZ* gene of the *E. coli* BL21 (DE3) genome and a non-targeting control spacer, constructing the pRoCascade_T (targeting) and pRoCascade_NT (non-targeting) vectors, respectively (**Table S6**). DNA fragments encoding the right and left RoCAST ends were synthesized (IDT) and cloned into the pUC19 vector flanking a *cmr* gene, yielding pRoDonor (**Table S6**). A 105-bp long DNA fragment from the *Rippkaea orientalis* genome, encoding the region which is located right upstream of the left end of RoCAST and includes the last 74 bp of the *tRNA-Leu* gene, was synthesized (IDT) and cloned into the pCDFDuet-1 vector, resulting in the construction of the pRoTarget vector (**Table S6**).

PAM-DETECT

Methods S1 contains a protocol for performing PAM-DETECT. A plasmid with five randomized nucleotides flanking a target site covering a *PacI* restriction enzyme recognition site was constructed as described before. If Cas proteins required for Cascade formation were encoded on separate plasmids, a MasterMix with the required Cas protein encoding plasmids in their stoichiometric amount was prepared beforehand. Thereby, a stoichiometry of Cas8_{e1}-Cse2₂-Cas7₆-Cas5₁-Cas6₁ was used for all Type I-E systems. A 6 μ L TXTL reaction was assembled consisting of 3-nM (high-Cascade) or 0.25-nM (low-Cascade) of the Cascade-encoding plasmid or the Cascade MasterMix, 4.5 μ L myTXTL Sigma 70 Master Mix, 0.2 nM pET28a_T7RNAP, 0.5 mM IPTG, 1 nM gRNA-encoding plasmid and 1 nM pPAM_library. A negative control containing all components from the reaction besides the Cascade plasmids and the gRNA-expressing plasmid was included. PAM-DETECT assays assessing either the type I-C or the type I-F1 system in *X. albilineans* were lacking IPTG in their reactions. TXTL

reactions were incubated at 29°C for 6 h or 16 h. The samples were diluted 1:400 in nuclease-free H₂O. 500 µL were digested at 37°C with Pacl (NEB) at 0.09 units/µL in 1x CutSmart Buffer (NEB) for 1 h and 500 µL were used as a “non-digested” control by adding nuclease-free H₂O instead of Pacl. After inactivation of Pacl at 65°C for 20 min, 0.05 mg/mL proteinase K (Cytiva) was added and incubated at 45°C for 1 h. After inactivation of Proteinase K at 95°C for 5 min, remaining plasmids were extracted via standard EtOH precipitation. Illumina adapters with unique dual indices were added by two amplification steps with KAPA HiFi HotStart Library Amplification Kit (KAPA Biosystems) and purified by AMPure XP (Beckman Coulter) after every PCR reaction. The first PCR reaction adds the Illumina sequencing primer sites with primers that can be found in **Table S6** using 15 µL of the EtOH-purified samples in a 50 µL reaction and 19 cycles. The second PCR adds the unique dual indices and the flow cell binding sequence using 1 ng purified amplicons generated with the first PCR using 18 cycles. The samples were submitted for next-generation sequencing with 50 bp paired-end reads with 1.25 or 2.0 million reads per sample on an Illumina NovaSeq 6000 sequencer. PAM wheels were generated according to Leenay et al. (2016) and Ondov et al. (2011). Nucleotide enrichment plot generation was adapted to the PAM analysis script from Marshall et al. (2018) by changing the script to visualize the probability of a given nucleotide at a given position. We started by normalizing the read counts of every PAM with the total number of reads. Next, we calculated the fold change for every PAM by determining the ratio of digested sample reads over undigested sample reads. The ratios for a given nucleotide at a given position were added up and divided by the sum of the ratios of all nucleotides at that given position and multiplied by 100. 25% represents no enrichment/depletion. All PAM-DETECT assays were done in duplicates and PAM wheel and nucleotide enrichment plots show averages. The generated NGS data have been deposited in NCBI's Gene Expression Omnibus (Edgar et al., 2002) and are accessible through GEO Series accession number GSE179614 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE179614>).

qPCR analysis of PAM-DETECT

To assess the remaining amount of PAM-library containing plasmid after conducting PAM-DETECT, qPCR was performed using SsoAdvanced Universal SYBR Green Supermix (Biorad) in 10 µL reactions. The reactions were quantified using a QuantStudio Real-Time PCR System (Thermo Fisher) with an annealing temperature of 68°C according to manufacturers' instructions. All samples were prepared by using the liquid handling machine Echo525 (Beckman Coulter).

deGFP repression assays in TXTL

To assess activity of CRISPR-Cas systems, deGFP-repression assays in 3 μ L TXTL reactions were conducted, measuring deGFP-expression over time in a 96-well V-bottom plate with BioTek Synergy H1 plate reader (BioTek) at 485/528 nm excitation/emission (Shin and Noireaux, 2012). All TXTL samples were either prepared by hand or by using the liquid handling machine Echo525 (Beckman Coulter).

3 μ L TXTL reactions for PAM validation assays were prepared containing Cascade plasmid concentrations according to **Table S2**. If Cas proteins required for Cascade formation were encoded on separate plasmids, a MasterMix with the required Cas protein encoding plasmids in their stoichiometric amount was prepared beforehand. Thereby, a stoichiometry of Cas5₁-Cas8₁-Cas7₇ was used for *X. albilineans* type I-C, Cas8f1₁-Cas5f1₁-Cas7f1₆-Cas6f₁ was used for *X. albilineans* type I-F1 and Cas8e₁-Cse2₂-Cas7₆-Cas5₁-Cas6₁ was used for all type I-E systems. Other components included in the TXTL reactions were 2.25 μ L myTXTL Sigma 70 Master Mix, 0.2 nM p70a_T7RNAP, 0.5 mM IPTG and 1 nM gRNA-encoding plasmid. After a 4 h pre-incubation at 29°C or 37°C that allowed the ribonucleoprotein complex of Cascade and crRNA to form, 1 nM reporter plasmid (pGFP_XXXXX) with various PAM sequences in close proximity to the promoter driving deGFP expression was added to the reaction to ensure Cascade-binding would lead to deGFP inhibition. The reactions were incubated for additional 16 h at 29°C or 37°C while measuring deGFP expression. The gRNAs were constructed to target a protospacer within the *degfp* promoter located adjacent to the various PAM sequences.

To test the cleavage and/or binding ability of the type I-C and the type I-F1 systems in *X. albilineans*, 3 μ L TXTL assays were conducted containing Cascade-encoding plasmids in the stoichiometry as mentioned before. To test binding ability, 2.25 μ L myTXTL Sigma 70 Master Mix, 0.2 nM p70a_T7RNAP, 0.5 mM IPTG, 1 nM gRNA1-, gRNA2-, gRNA6-, or gRNAnt-encoding plasmid and 1 nM or 0.25 nM Cascade MasterMix was added to a TXTL reaction for the type I-C and type I-F1 system, respectively. To test cleavage ability, 2.25 μ L myTXTL Sigma 70 Master Mix, 0.2 nM p70a_T7RNAP, 0.5 mM IPTG, 1 nM gRNA1-, gRNA2, gRNA4, gRNA5, or gRNAnt-encoding plasmid, 1 nM Cascade MasterMix and 0.5 nM or 0.25 nM pXalb_IC_Cas3 or pXalb_IF_Cas2-3 was added to a TXTL reaction for the type I-C and type I-F1 system, respectively. After a 4 h pre-expression at 29°C, 1 nM p70a_deGFP reporter plasmid, p70a_deGFP_ICST1, p70a_deGFP_ICST2, p70a_deGFP_IF1ST1, or p70a_deGFP_IF1ST2 was added to the reactions and incubated for additional 16 h at 29°C while measuring deGFP-fluorescence. gRNA1 is designed to target a protospacer within the promoter driving deGFP expression adjacent to a type I-C TTC or a type I-F1 CC PAM to ensure Cascade-binding would lead to deGFP-inhibition. gRNA2, gRNA4 and gRNA5 were

designed to target a protospacer adjacent to a type I-C TTC or a type I-F1 CC PAM upstream of the promoter to ensure cleavage of the targeted plasmid would result in deGFP-inhibition whereas binding-only would result in deGFP-production. gRNAnt represents a non-targeting control.

Prophage prediction

Prophage regions in the genome of *X. albilineans* CFBP7063 were predicted using VirSorter v1.0.3 (Roux et al., 2015). Prophage sequences with category 5 and 6 were found and are shown in **Figure S2A**.

Transposition in TXTL

To assess crRNA-dependent transposition of the *Vibrio cholerae* Tn6677 I-F CAST in TXTL, 5 μ L TXTL reactions containing 3.75 μ L myTXTL Sigma 70 Master Mix, 0.2 nM p70a_T7RNAP, 0.5 mM IPTG, 1 nM of the previously described donor plasmid (pSL0527), 2 nM of the previously described TnsABC-plasmid (pSL0283) (Klompe et al., 2019), 1 nM p70a_deGFP and 1 nM pVch_IF_CasQ_gRNA3 or pVch_IF_CasQ_gRNAnt were prepared. The reactions were incubated at 29°C for 16 h. Transposition events were detected in a 1:400 dilution of the TXTL reaction by PCR amplification using Q5 Hot Start High-Fidelity 2X Master Mix (NEB) and combinations of donor DNA and genome specific primers. Transposition was verified by Sanger sequencing (**Table S6**).

crRNA-independent transposition of RoCAST in TXTL was performed in 3 μ L TXTL reactions consisting of 2.25 μ L myTXTL Sigma 70 Master Mix, 0.2 nM p70a_T7RNAP, 0.5 mM IPTG, 1 nM pRoTarget, 1 nM pRoDonor and 1 nM pRoTnsABC, pRoTnsABCD, pRoTnsABCQ or pRoTnsABCDQ. The reactions were incubated at 29°C for 16 h. Transposition events were detected in a 1:100 dilution of the TXTL reaction by PCR amplification using Q5 Hot Start High-Fidelity 2X Master Mix (NEB) and combinations of donor DNA and genome specific primers (**Table S6**). Transposition was verified by Sanger sequencing.

qPCR analysis of VcCAST transposition efficiency in TXTL

Pairs of VcCAST cargo and target plasmid-specific primers were designed to amplify 106-151 bp long fragments, resulting from VcCAST induced transposition in either orientation in TXTL reactions. The qPCR reactions were performed using SsoAdvanced Universal SYBR Green Supermix (Biorad) in 10 μ L reactions. The reactions were quantified using a QuantStudio Real-Time PCR System (Thermo Fisher) with an annealing temperature of 60°C according to manufacturers' instructions.

We cloned the VcCAST cargo from the donor plasmid (pSL0527) into a position 50 bp downstream of the protospacer in the pGFP_GTACC target plasmid. The cargo was cloned in

both orientations (left to right and right to left transposon end) resulting in the construction of the pGFP_GTACC_LR and pGFP_GTACC_RL plasmids that mimic the two products of successful VcCAST-based transposition in TXTL. We then performed control TXTL transposition reactions, as previously described, altering the ratios of pGFP_GTACC to pGFP_GTACC_LR or pGFP_GTACC_RL plasmids in each reaction simulating variable transposition efficiencies. We tested the qPCR primer pairs with each of the control TXTL reactions and we detected transposition products in either orientation and at efficiencies as low as 0.5%.

We performed TXTL transposition reactions, as previously described, using either a targeting or a non-targeting gRNA expressing plasmid and three target plasmids with distinct PAM sequences (ACC, CAA, and AAA respectively) as their defining difference (**Table S5**). Samples from each TXTL reaction were analyzed by qPCR. The transposition efficiency for each reaction and for each primer pair/orientation was calculated as $2^{-\Delta\Delta Ct}$, where $\Delta\Delta Ct$ was the difference between the ΔCt of an experimental TXTL reaction and a control TXTL reaction that contained either the pGFP_GTACC_LR or the pGFP_GTACC_RL as the only target plasmid (**Table S5**).

Transposition *in vivo*

For the crRNA-dependent transposition *in vivo* using the I-F CAST from *Vibrio cholerae* Tn6677, we employed the previously described transposition system (Klompe et al., 2019). We electroporated 30 ng of the pSL0283 vector with 30 ng of the pSL0527 vector and 30 ng of either the pQCas_CAA or pQCas_AAA vector into *E. coli* BL21(DE3) electrocompetent cells. We plated a fraction of each electroporation mixture on 100 mg/mL ampicillin, 50 mg/mL spectinomycin, 50 mg/mL kanamycin, 0.1 mM IPTG and 100 μ g/mL X-gal containing LB-agar plates. The plates were incubated for 24 h at 30°C and the formed colonies were subjected to blue/white screening. Transposition events were identified by colony PCR using Q5 Hot Start High-Fidelity 2X Master Mix (NEB) and genome specific primers (**Table S6**).

For the crRNA-dependent transposition *in vivo* using RoCAST, we electroporated 30 ng of either pRoCascade_T or pRoCascade_NT vector with 30 ng of pRoDonor and 30 ng of either pRoTnsABC, pRoTnsABCD, pRoTnsABCQ or pRoTnsABCDQ vector into *E. coli* BL21(DE3) electrocompetent cells. We plated a fraction of each electroporation mixture on 100 mg/mL ampicillin, 50 mg/mL spectinomycin, and 50 mg/mL kanamycin containing LB-agar plates. The plates were incubated for 20 h at 37°C and the formed colonies were scraped and resuspended in LB liquid medium. A fraction of each cell suspension was re-plated on LB-agar plates supplemented with 100 mg/mL ampicillin, 50 mg/mL spectinomycin, 50 mg/mL kanamycin and 0.01 mM IPTG for induction of the expression of the Cascade and transposase proteins. The

plates were incubated 20 h at 37°C and all the formed colonies were scraped and resuspended in LB liquid medium. A fraction of each cell suspension was subjected to gDNA isolation using the illustra Bacteria genomicPrep Mini Spin Kit (Cytiva). Transposition events were identified by PCR using Q5 Hot Start High-Fidelity 2X Master Mix (NEB) and combinations of donor DNA and genome specific primers (**Table S6**).

For the crRNA-independent *in vivo* transposition using RoCAST, we electroporated 30 ng of the pRoTarget with 30 ng of pRoDonor and 30 ng of either the pRoTnsABC, pRoTnsABCD, pRoTnsABCQ or pRoTnsABCDQ vector into *E. coli* BL21(DE3) electrocompetent cells. We plated a fraction of each electroporation mixture on 100 mg/mL ampicillin, 50 mg/mL spectinomycin, and 50 mg/mL kanamycin containing LB-agar plates. The plates were incubated for 20 h at 37°C and the formed colonies were scraped and resuspended in LB liquid medium. A fraction of each cell suspension was re-plated on LB-agar plates supplemented with 100 mg/mL ampicillin, 50 mg/mL spectinomycin, 50 mg/mL kanamycin and 0.01 mM IPTG for induction of the expression of the transposase proteins. The plates were incubated 20 h at 37°C and all the formed colonies were scraped and resuspended in LB liquid medium. A fraction of each cell suspension was subjected to gDNA isolation using the illustra Bacteria genomicPrep Mini Spin Kit (Cytiva). Transposition events were identified by PCR using Q5 Hot Start High-Fidelity 2X Master Mix (NEB) and combinations of donor DNA and pRoTarget specific primers (**Table S6**).

Assessing transposition insertion point

To assess the exact insertion point of *Rippkaea orientalis* I-B2.2 CAST, *in vivo* and *in vitro*, transposition assays were conducted as previously described and the transposition products were PCR amplified and sent for next-generation sequencing. Illumina adapters with unique dual indices were added by two amplification steps with KAPA HiFi HotStart Library Amplification Kit (KAPA Biosystems) and each amplicon was purified by AMPure XP (Beckman Coulter). The first PCR reaction adds the Illumina sequencing primer sites with primers that can be found in **Table S6**, the second PCR adds the unique dual indices and the flow cell binding sequences. 2 µL of 1:100 dilutions were used in a 50 µL PCR reaction to amplify TXTL reactions using either 19 or 30 cycles. 50 ng of genomic DNA were used in a 50 µL PCR reaction to amplify *in vivo* transposition with either 19 or 30 cycles. 1 ng of purified TXTL or *in vivo*-amplicon were subjected to the second PCR using 18 cycles.

Library-pools consisting of six samples were submitted for next-generation sequencing with 300 bp paired-end reads with 0.15 million reads on an Illumina MiSeq machine.

The generated NGS data have been deposited in NCBI's Gene Expression Omnibus (Edgar et al., 2002) and are accessible through GEO Series accession number GSE179614 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE179614>).

Quantification and statistical analysis

deGFP repression assays in TXTL

The fluorescence background was subtracted from the endpoint deGFP values with TXTL samples consisting of only myTXTL Sigma 70 Master Mix and nuclease-free water. The resulting endpoint deGFP values were either depicted as averages of a targeting gRNA and a non-targeting gRNA or fold change-repression was calculated by the ratio of non-targeting over the targeting deGFP values. Significance was calculated with Welch's t-test. $P > 0.05$ is shown as ns, $P < 0.05$ is shown as *, $P < 0.01$ is shown as ** and $P < 0.001$ is shown as ***. Within the PAM validation assays represented as fold changes, significance was calculated between the fold change of a given PAM and the fold change of a PAM that corresponds to the 3' end of the repeat of the tested CRISPR system. The fold changes of the PAM validation in **Figure 3B** are depicted in a heat map. Thereby a difference between a non-targeting sample and a targeting sample with a specific PAM resulting in $P > 0.05$ is shown in white and excluded from further analysis. For all other samples within the heat map, the fold changes were calculated as mentioned above and presented relative to the highest fold change within one system. Significance within the deGFP repression assays testing binding and cleavage ability of the type I-C and the type I-F1 system in *X. albilineans* was calculated with the targeting and non-targeting sample for each condition. For the endpoint measurements in **Figure 5C**, significance was calculated between a non-targeting sample and a targeting sample targeting the same PAM.

qPCR analysis for PAM-DETECT

Cq values were used to measure target amounts. To calculate the relative abundance of the PAM library containing plasmid in the digested sample to the non-digested sample, the relative plasmid amount was normalized to a control amplifying the pET28a-T7RNAP that has no PacI recognition site using the $2^{-\Delta\Delta C_t}$ method. Significance to the control sample lacking a CRISPR-Cas system was calculated with Welch's t-test. $P > 0.05$ is shown as ns, $P < 0.05$ is shown as *, $P < 0.01$ is shown as ** and $P < 0.001$ is shown as ***.

Assessing transposition insertion point

~15 nts long sequences 5' of the transposon terminal left end were extracted, counted and sorted. The sequences were mapped to the targeted plasmid or the targeted genome tolerating

2 nts mismatches and the distance between the insertion point and the PAM upstream of the protospacer or the end of the *tRNA-Leu* gene was noted. To only depict reliable insertion points, we present insertion points with more than 20 reads. The insertion points are shown as bar graphs.

The processed NGS data have been deposited in NCBI's Gene Expression Omnibus (Edgar et al., 2002) and are accessible through GEO Series accession number GSE179614 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE179614>).

***In silico* selection of representative type I-E CRISPR-Cas systems for PAM-DETECT**

HMM profiles for the Cas5e, Cas6e, Cas7e and Cas8e proteins were developed upon aligning the members of the corresponding protein families (Cas5e: pfam09704, TIGR1868, TIGR02593; Cas6e: pfam08798, TIGR01907; Cas7e: pfam09344, TIGR01869; Cas8e: pfam09481, TIGR02547). A new HMM profile was generated for the less conserved Cse2 protein upon aligning sequences with known 3D structure using PROMALS3D server (Pei et al., 2008) followed by a series of iterative alignment/model building steps to include additional sequences and increase sequence diversity. For the aligning processes of all five proteins, sequences were dereplicated at 90% identity using cd-hit (Huang et al., 2010) (with options -c 0.90 -g 1 -aS 0.9). The dereplicated sequences were compared against each other using blastp from blast+ v2.6.0 (Altschul et al., 1990) with e-value 10e-05 and defaults for the rest of parameters. Hits were filtered to retain those at $\geq 60\%$ pairwise identity, and were next clustered using the mcl algorithm (Enright et al., 2002) with inflation parameter of 2.0. Clusters with ≥ 10 members were aligned using Gismo (Neuwald and Liu, 2004) with default parameters, and consensus sequences were extracted from the alignments. These consensus sequences, as well as singletons and sequences from smaller clusters were aligned using Gismo (Neuwald and Liu, 2004). Alignments were manually curated to remove shorter sequences that did not have one or more of the active site positions and HMM profiles were generated using hmmbuild (Eddy, 2009). Hmmssearch (Eddy, 2009) using the generated HMM profiles against all public genomes (isolates, SAGs, and MAGs), and all public metagenomes resulted in hits which were subsequently aligned against the generated HMM profiles. After selecting gene arrays that have all five complete or nearly complete genes, we identified 6,964 arrays in public genomes and 5,000 arrays in public metagenomes. Aligned sequences for all proteins from the same array were concatenated, and the resulting sequences were dereplicated with cd-hit (Huang et al., 2010) at 90% identity, aligned over at least 90% of the shorter sequences. This resulted in 2,851 clusters, 1,799 from metagenomes and 1,052 from genomes. Whereas the alignment of the Cas8e proteins from these clusters showed high variability, the predicted L1 helix regions of the Cas8e, which have been shown to directly interact with the PAM (Xiao et al., 2017),

presented higher conservation. We generated a list with the L1 signatures from the de-replicated cluster set and we subsequently manually filtered out systems that do not belong to known cultured mesophilic bacteria (**Table S3**). From the resulting list we selected I-E CRISPR/Cas systems with a variety of L1 motifs for experimental validation with PAM-DETECT.

Comparative analysis of I-B CAST transposases

We searched previous literature (Peters et al., 2017; Saito et al., 2021) for *in silico* identified I-B2 CASTs, which contain a fused *tnsAB* gene and are easily distinguished from I-B1 CASTs, which contain separate *tnsA* and *tnsB* genes. We observed that one clade of the I-B2 CASTs encompasses systems with *tnsAB-tnsC-tnsD* operons while having the *tniQ* gene separated, whereas the other clade encompasses systems with *tnsAB-tnsC-tniQ* operons and the *tnsD* gene separated. We denoted the systems in the former clade as I-B2.1 CASTs and in the latter clade as I-B2.2 CASTs. We focused on the I-B2.2 CAST clade, that has no *in vitro* or *in vivo* characterized members, and we discarded from further analysis the systems that lacked at least one of the CRISPR-Cas or transposition genes (*tnsAB*, *tnsC*, *tnsD*, *tniQ*, *cas5*, *cas6*, *cas7*, *cas8*). We performed BlastP search (Altschul et al., 1990) using the TnsAB, TnsC, TnsD, TniQ proteins of each selected I-B2.2 system as queries, aiming to identify additional I-B2.2 CAST candidates. Our analysis yielded in total seven I-B2.2 systems and we selected six previously described I-B2.1 systems for phylogenetic analysis (Saito et al., 2021). The alignment of I-B2.1 and I-B2.2 transposition proteins was performed using T-Coffee (Di Tommaso et al., 2011), the phylogenetic trees were built using average distance and the BLOSUM62 matrix and they were visualized with JalView (Waterhouse et al., 2009).

***In silico* analysis of RoCAST**

We predicted the CRISPR array of RoCAST by uploading the *Rippkaea orientalis* genomic region between the *Rocas5* and *RotniQ* to CRISPRFinder (Grissa et al., 2007). The RoCAST ends were determined manually on Benchling by searching for repeat sequences of 20 nucleotides, with maximum 5 mismatched nucleotides, within the *R. orientalis* genomic regions 1 kb upstream of the *RotnsAB* and 1 kb downstream of the *RotnsD*. We identified two types of repeat sequences present in both regions in opposite orientations and a candidate duplication region. Notably, we identified five repeat sequences in the predicted left end region, with one of the repeat sequences located downstream of the predicted duplication site, hence outside of the predicted RoCAST limits. The TXTL transposition demonstrated that this repeat is not part of the RoCAST transposon.

Supplementary Information

Supplementary figures

Figure S1: Additional type I-E CRISPR-Cas systems subjected to PAM-DETECT. Related to **Figure 3.** (A) Extent of PAM library protection for the mined I-E CRISPR-Cas systems. Error bars indicate the mean and standard deviation of triplicate independent experiments. ***: $p < 0.001$. **: $p < 0.01$. *: $p < 0.05$. ns: $p > 0.05$. (B) Nucleotide-enrichment plots and PAM wheels based on conducting PAM-DETECT with Cascade from additional I-E CRISPR-Cas systems. Individual sequences comprising at least 2% of the PAM wheel are shown. Results represent the average of duplicate independent experiments.

Figure S2: Genomic target sites, predicted prophage regions, library protection and cleavage of genomic target sites for the I-C and I-F1 CRISPR-Cas systems in *Xanthomonas albilineans*. Related to **Figure 4**. **(A)** Genomic architecture of the two CRISPR-Cas systems, their self-targets, and location of predicted prophage regions. The numbering of the arrays corresponds to those in **Figure 4A**. Placement of the ovals indicates whether the self-target corresponding to the spacer sequence is located on the top or bottom strand of the chromosome or plasmid. Prophage regions were predicted with VirSorter (Roux et al., 2015). **(B)** Extent of PAM library protection for both CRISPR-Cas systems. **(C)** Functional targeting in TXTL using native spacer:self-target pairs from *X. albilineans*. The origin of the native spacers is indicated below the graphs. Fold-change was calculated based on a non-targeting crRNA control. The non-targeting crRNA control is the reference for statistical analyses.

Error bars in B and C indicate the mean and standard deviation of triplicate independent experiments. ***: $p < 0.001$. **: $p < 0.01$. *: $p < 0.05$. ns: $p > 0.05$.

Figure S3: Further characterization of the *Vibrio cholerae* I-F CRISPR transposon. Related to **Figure 5**. **(A)** Extent of PAM library protection with Cascade from the VcCAST under different conditions. The low-Cascade conditions (0.25-nM plasmid, 6-h reaction time) was the basis of the PAM-DETECT output reported in **Figure 5B**. **(B)** Nucleotide-enrichment plot and PAM wheel based on conducting PAM-DETECT with Cascade and TniQ under high-Cascade conditions (3-nM plasmid, 16-h reaction time). Individual sequences comprising at least 1% of the PAM wheel are shown. The plot and PAM wheel are averages of duplicate independent experiments. **(C)** Dispensability of TniQ for Cascade binding in TXTL-based PAM validation assay. The TXTL-based deGFP repression assay performed in **Figure 5C** was conducted using Cascade alone. ATAAC matches the 3' end of the repeat and therefore serves as a negative control. The ATAAC self PAM is the reference for statistical analyses. **(D)** Target locations within the *lacZ* gene associated with a CAA or AAA PAM. The locations are shifted by a single base. See **Figure 5E** for the extent of transposition for either site based on formation of blue or white colonies. **(E)** Colony PCR of representative colonies associated with the CAA or AAA PAM targets. Only white colonies were picked for CAA and only blue colonies were picked for AAA in part because colonies of the opposite color were rarely observed (see **Figure 5E**). The markers indicate the expected band sizes based on successful transposition or no transposition. Error bars in A and B indicate the mean and standard deviation of triplicate independent experiments. ***: $p < 0.001$. **: $p < 0.01$. *: $p < 0.05$. ns: $p > 0.05$.

Figure S4: Interrogating the *Rippkaea orientalis* I-B2.2 CRISPR transposon. Related to **Figure 6**. **(A)** Sequence alignments of the TnsAB, TnsC, TnsD, and TniQ proteins from six previously reported I-B2.1 CAST systems and the seven I-B2.2 CAST systems identified in this study. The alignments were built with T-Coffee (Di Tommaso et al., 2011), visualized with Jalview and ordered according to the trees presented in **Figure 6A**. The conservation (Cr), quality (Qu), consensus (Cu), and occupancy (Oc) histograms from Jalview are presented below each alignment. The alignments are colored using the ClustalX color palette. Pmc: *Peltigera membranacea cyanobiont* 210A. Np: *Nostoc punctiforme* NIES-2108. Nc: *Nostoc carneum* NIES-207. Ss: *Stanieria* sp. NIES-3757. Ns3: *Nostoc* sp. NIES-3756. Ns2: *Nostoc* sp. NIES-2111. Ps: *Planktothrix sarta*. Cos: *Coleofasciculus* sp. FACHB-SPT9. Ns9: *Nostoc* sp. NMS9. Ns54: *Nostoc* sp. CENA543. Ns52: *Nostoc* sp. C052. Chs: *Chroococcus* sp. FPU101. Ro: *Rippkaea orientalis*. Names in black and in red are associated with the I-B2.1 and I-B2.2 branch, respectively. **(B)** Extent of PAM library protection with Cascade from the *R. orientalis* CAST (RoCAST) under different conditions. The low-Cascade condition (0.25-nM plasmid, 16-h reaction time) was the basis of the PAM-DETECT output reported in **Figure 6B**. Error bars indicate the mean and standard deviation of triplicate independent experiments. ***: $p < 0.001$. **: $p < 0.01$. *: $p < 0.05$. ns: $p > 0.05$. **(C)** Nucleotide-enrichment plot and PAM wheel based on conducting PAM-DETECT with Cascade under high-Cascade conditions (3-nM Cascade plasmid, 16-h reaction time). Individual sequences comprising at least 2% of the PAM wheel are shown. The plot and PAM wheel are averages of duplicate independent experiments. See **Figure 6B** for the PAM-DETECT output with Cascade under low-Cascade conditions (0.25-nM Cascade plasmid, 16-h reaction time).

Figure S5: TXTL-based PAM determination and DNA transposition for the *Anabaena variabilis* ATCC 29413 I-B1 CRISPR transposon. Related to **Figure 6** and **7**. **(A)** The I-B1 CRISPR transposon from *A. variabilis* ATCC 29413 (AvCAST). **(B)** Nucleotide-enrichment plot and PAM wheel based on conducting PAM-DETECT with high-Cascade conditions (3-nM plasmid, 16-h reaction time). Individual sequences comprising at least 2% of the PAM wheel are shown. The plot and PAM wheel are averages of duplicate independent experiments. The predominant PAM (AT) matches that identified in recent work in *E. coli* (Saito et al., 2021). **(C)** CRISPR-dependent transposition with the AvCAST in TXTL. The crRNA target was flanked by an AT PAM. Transposition only occurred in the presence of TniQ.

Figure S6: CRISPR-dependent transposition by the *V. cholerae* I-F CRISPR transposon and the *R. orientalis* I-B2.2 CRISPR transposon. Related to **Figure 7**. **(A)** CRISPR-dependent transposition with the *V. cholerae* CRISPR transposon (VcCAST) in TXTL. Top: transposition with a targeting (T) or non-targeting (NT) crRNA. Transposition was determined by amplifying across the junction of the target and inserted donor DNA. Bottom: Determination of transposon ends and insertion distance by Sanger sequencing. **(B)** CRISPR-dependent transposition with and without TniQ and TnsD with the *R. orientalis* I-B2.2 CRISPR transposon (RoCAST) in TXTL. Transposition was determined by next-generation sequencing of the PCR product spanning the crRNA target site and the beginning of the cargo (left-right orientation). **(C)** CRISPR-dependent transposition with and without TniQ with the *R. orientalis* I-B2.2 CRISPR transposon (RoCAST) in *E. coli*. Transposition was determined by next-generation sequencing of the PCR product spanning the crRNA target site and the beginning of the cargo (left-right orientation).

Supplementary tables

Table S1: Extent of PAM determination for type I CRISPR-Cas systems. Studies that tested at least 40 PAM sequences were included. Related to **Figure 1**.

| System type | Organism | Number of tested PAMs | Method | Source |
|-------------|-----------------------|-----------------------|------------------------------------------------------------|------------------------|
| I-A | <i>P. furiosus</i> | 64 | Individual plasmids tested with plasmid interference assay | (Elmore et al., 2015) |
| I-B | <i>H. volcanii</i> | 62 | Individual plasmids tested with plasmid interference assay | (Fischer et al., 2012) |
| I-B | <i>H. hispanica</i> | 64 | Individual plasmids tested with plasmid interference assay | (Li et al., 2014) |
| I-C | <i>B. halodurans</i> | 256 | Library screening with PAMSCANR | (Leenay et al., 2016) |
| I-C | <i>L. pneumophila</i> | 64 | Library screening with plasmid interference assay | (Rao et al., 2017) |

Table S1 (continued)

| System type | Organism | Number of tested PAMs | Method | Source |
|-------------|----------------------|-----------------------|-------------------------------------------------------------------|----------------------------|
| I-D | <i>M. aeruginosa</i> | 256 | Library screening with plasmid interference assay | (Osakabe et al., 2020) |
| I-E | <i>E. coli</i> | 256 | Library screening with PAMS-CANR | (Leenay et al., 2016) |
| I-E | <i>E. coli</i> | 64 | Library screening with plasmid loss assay | (Musharova et al., 2019) |
| I-E | <i>E. coli</i> | 256 | crRNA library targeting bacterial genome | (Fu et al., 2017) |
| I-E | <i>E. coli</i> | 40 | PAM-protospacer library screening with plasmid interference assay | (Fineran et al., 2014) |
| I-E | <i>E. coli</i> | 64 | Library screening with plasmid interference assay | (Xue et al., 2015) |
| I-E | <i>E. coli</i> | 64 | Library screening with phagemid transduction assay | (Caliando and Voigt, 2015) |
| I-E | <i>T. fusca</i> | 4,096 | Library screening with CHAMP | (Jung et al., 2017) |
| I-F | <i>Z. mobilis</i> | 64 | Individual plasmids tested with plasmid interference assay | (Zheng et al., 2019) |
| I-G | <i>P. furiosus</i> | 64 | Individual plasmids tested with plasmid interference assay | (Elmore et al., 2015) |

Table S2: Cascade concentrations used in the TXTL-based PAM validation assays. If proteins required for Cascade formation were not encoded as an operon on one plasmid but encoded on separate plasmids, a MasterMix with all required plasmids in their stoichiometric amount was prepared beforehand (Cascade-MM). Related to **Figures 2, 3, 4, 5 and 6.**

| System | Cascade-MM | Operon | Final concentration | Reaction Temperature |
|---------------------------------------------------------|------------|--------|---------------------|----------------------|
| <i>E. coli</i> type I-E | x | | 0.5 nM | 29 °C |
| <i>Azotobacter chroococcum</i> (Ac2) type I-E | x | | 2 nM | 29 °C |
| <i>Azotobacter chroococcum</i> (Ac3) type I-E | x | | 1 nM | 29 °C |
| <i>Leptothrix mobilis</i> (Lm) type I-E | x | | 2 nM | 29 °C |
| <i>Ectothiorhodospira haloalkaliphila</i> (Eh) type I-E | x | | 0.5 nM | 29 °C |
| <i>Marinomonas</i> sp. (Ms) type I-E | x | | 0.5 nM | 29 °C |
| <i>Streptococcus thermophilus</i> (St) type I-E | x | | 1 nM | 37 °C |
| <i>X. albilineans</i> type I-C | x | | 0.5 nM | 29 °C |
| <i>X. albilineans</i> type I-F1 | x | | 0.25 nM | 29 °C |
| <i>V. cholerae</i> I-F CAST | | x | 0.5 nM | 29 °C |
| <i>Rippkaea orientalis</i> I-B CAST | | x | 0.25 nM | 29 °C |

Table S3: Cas8e proteins and the variable L1 loop from diverse I-E CRISPR-Cas systems from cultured mesophilic bacterial strains, related to Figure 3.

Supplementary methods S1

Detailed protocol for PAM-DETECT. (Related to STAR Methods).

Reagents

- 100% EtOH
- 3M sodium acetate, pH 5.2
- 70% EtOH
- AMPure XP (Beckman Coulter)
- CutSmart Buffer (NEB)
- KAPA HiFi HotStart ReadyMix PCR Kit (KAPA Biosystems)
- myTXTL Sigma 70 Master Mix Kit (Arbor Bioscience)
- PacI (NEB)
- Proteinase K (20 mg/μL) (Cytiva)

Procedure

PAM assay

1. Prepare 6-μL TXTL reaction on ice with the following composition:

| Compound | Final concentration/amount |
|--------------------------------------|----------------------------------------------|
| myTXTL | 4.5 μL |
| Cascade encoding plasmid / MasterMix | 3 nM (high-Cascade) or 0.25 nM (low-Cascade) |
| gRNA-encoding plasmid* | 1 nM |
| pPAM_library | 1 nM |
| pET28a_T7RNAP (if necessary) | 0.2 nM |
| IPTG (if necessary) | 0.5 nM |
| Nuclease-free H ₂ O | add to total volume of 6 μL |

*If the gRNA and Cascade are encoded on the same plasmid, add the Cascade/gRNA plasmid at a final concentration of 3 nM or 0.25 nM.

2. Mix carefully and spin down briefly.
3. Incubate at 29°C for 16 h (high-Cascade) or 6 h (low-Cascade).
4. Mix carefully and spin down briefly.
5. Dilute samples 1:400 in nuclease-free H₂O and place on ice.
6. Prepare digestion reaction with the following composition:

| Compound | Final concentration/amount |
|---------------------|----------------------------|
| Diluted TXTL sample | 500 μ L |
| CutSmart Buffer | 1x |
| Pacl** | 0.09 units/ μ L |

**Also prepare a “non-digested” control for every TXTL reaction with H₂O instead of Pacl.

7. Incubate digestion reaction at 37°C for 1 h.
8. Inactivate digestion reaction at 65°C for 20 min.
9. Prepare Proteinase K reaction by adding proteinase K to the digestion reaction with a final concentration of 0.05 mg/mL.
10. Incubate proteinase K reaction at 45°C for 1 h.
11. Inactivate proteinase K reaction at 95°C for 5 min.

EtOH precipitation

12. Split each sample in two equal parts to ensure EtOH precipitation can be carried out in 1.5 mL tubes.
13. Prepare EtOH precipitation as follows:

| Compound | Final amount |
|---------------------------|--------------|
| Split sample | 1 volume |
| 3M sodium acetate, pH 5.2 | 0.1 volumes |
| 100% EtOH, ice cold | 2.5 volume |

14. Mix vigorously by vortexing.
15. Place at -80 °C for 20 min or longer.
16. Spin samples at 4°C for 15 min at maximum speed.
17. Discard liquid carefully.
18. Add 200 μ L of ice-cold 70% EtOH.
19. Spin samples at 4°C for 10 min at maximum speed.
20. Repeat steps 17-19.
21. Carefully remove liquid completely.
22. Evaporate remaining liquid by drying the pellet at 50°C.
23. Add 10 μ L nuclease-free H₂O.
24. Incubate at 65°C for 10 min.
25. Vortex thoroughly.
26. Recombine divided samples.

NGS library preparation

27. Prepare a 50 μ L PCR reaction to add Illumina sequencing primer sites (Primers in **Table S6**) to the EtOH-purified samples:

| Compound | Final concentration/amount |
|----------------------------------|-----------------------------------|
| KAPA HiFi HotStart ReadyMix (2x) | 1x |
| Forward primer | 1 μ M |
| Reverse primer | 1 μ M |
| EtOH-purified sample | 15 μ L |

28. Run the PCR at 62°C annealing temperature and 19 cycles.

29. Purify the PCR reaction with AMPure XP beads.

30. Prepare a 50- μ L PCR reaction to add unique dual indices and the flow cell binding site to the amplicons:

| Compound | Final concentration |
|-----------------------------------|----------------------------|
| KAPA HiFi HotStart ReadyMix (2x) | 1x |
| Forward primer | 1 μ M |
| Reverse primer | 1 μ M |
| Amplicons purified with AMPure XP | 1 ng |

31. Run the PCR at appropriate annealing temperature and 18 cycles.

32. Purify the PCR reaction with AMPure XP beads.

33. Samples are now ready for NGS.

Chapter 4: Host-encoded anti-CRISPR proteins block DNA degradation by two extensively self-targeting CRISPR-Cas systems in *Xanthomonas albilineans*

Author contributions:

Abstract

CRISPR-Cas systems store fragments of invader DNA as spacers to recognize and clear those same invaders in the future. Spacers can also be acquired from the host's genomic DNA, leading to lethal self-targeting. While self-targeting can be circumvented through a range of mechanisms, natural examples have been interrogated rarely and normally in hosts with only one self-targeting system. Here, we investigate extensive self-targeting by two CRISPR-Cas systems encoding 24 self-targeting spacers in the plant pathogen *Xanthomonas albilineans*. We show that the native I-C and I-F1 systems are actively expressed based on transcriptomics analyses and proper CRISPR RNA processing. When expressed in *Escherichia coli*, each Cascade complex binds its target to block transcription, while the addition of Cas3 paired with genome targeting induces killing. To explain the lack of lethal self-targeting in *X. albilineans*, we predicted putative anti-CRISPR proteins (Acrs) encoded within the bacterium's genome. Screening of the candidates with cell-free transcription-translation systems and in *E. coli* revealed two Acrs, which we named AcrI11 and AcrIF12_{Xal}, that inhibited Cas3 but not Cascade of the respective system. These findings reveal how a bacterium tolerates extensive self-targeting through two CRISPR-Cas systems and expand the suite of Cas3-inhibiting Acrs.

Introduction

Bacteria and archaea employ a variety of methods to defend against invaders (1). Of these, the only known defenses conferring adaptive immunity are CRISPR-Cas systems. These systems are incredibly diverse, with two classes, six types and more than 30 subtypes defined to-date (2). Despite their diversity, CRISPR-Cas systems utilize three general steps for

adaptive immunity. First, CRISPR-Cas systems acquire short nucleic-acid fragments from invaders that are integrated as so-called spacers in between conserved repeats within CRISPR arrays (3, 4). Second, the CRISPR arrays are transcribed as long premature CRISPR RNAs (crRNAs) that are processed into mature crRNAs (5). Third, mature crRNAs guide the CRISPR effector proteins to a DNA or RNA region complementary to the spacer portion of the crRNA. Targets flanked by a protospacer-adjacent motif (PAM) or targets lacking complementarity with the repeat portion of the crRNA activate the nuclease (6–9). Activation then leads to either cleavage of the target that clears the invader or widespread collateral RNA cleavage that induces cellular dormancy (10–13).

The incorporation of new spacers during the acquisition step is generally biased towards foreign nucleic-acids, although accidental incorporation of genomic fragments as spacers can occur (14, 15). These self-targeting spacers would trigger a genomic attack that should be lethal and therefore selected against (12, 14, 16); nevertheless, these spacers are quite common, with about 20% of bacteria with a CRISPR-Cas system harboring one or multiple self-targeting spacers (15). To-date, several measures have been elucidated to explain how bacteria can evade autoimmunity triggered by self-targeting spacers (17). One measure is mutating *cas* genes to inhibit one or multiple steps of CRISPR-Cas targeting, although this outcome sacrifices the protective function of the CRISPR-Cas system (14, 18–20). Another measure is mutating or deleting the target region or the PAM next to it to avoid complementarity to the spacer and recognition by the CRISPR-Cas system (14, 21, 22). A third measure to avoid autoimmunity is to block expression of one of all *cas* genes to inactivate the CRISPR-Cas system. A final measure is inhibiting targeting by the CRISPR-Cas systems through anti-CRISPR proteins (Acrs), small and diverse proteins often encoded in prophages (15).

While the different measures are clear for how self-targeting can be averted, the exact mechanism in a given bacterium with a self-targeting system can be difficult to determine. Bioinformatic analyses can identify some measures, like mutations of *cas* genes or the target region, but not all, therefore experimental investigations are necessary. Nevertheless, exploration of bacteria with self-targeting spacers revealed new classes of Acrs and uncovered functions of CRISPR-Cas systems that extend beyond adaptive immunity (23–30). However, the few experimental investigations of self-targeting mostly focused on bacteria with a single CRISPR-Cas system and few self-targeting spacers (17). In this study, we investigated self-targeting by two type I CRISPR-Cas systems encoded in the plant pathogen *Xanthomonas albilineans* CFBP7063. Thereby, we discovered two endogenous Acrs that we named AcrIC11 and AcrIF12_{*Xal*} that inhibit either system's nuclease activity but not DNA binding activity. Our results uncover how *X. albilineans* likely escapes extensive self-targeting through two orthogonal CRISPR-Cas systems and expand the small set of known Cas3-inhibiting Acrs.

Results

The two self-targeting CRISPR-Cas systems in *Xanthomonas albilineans* do not avoid self-targeting through gene repression

Xanthomonas albilineans encodes two CRISPR-Cas systems, a type I-C system and a type I-F1 system, along with six CRISPR arrays. Of these arrays, one is associated with the type I-C system and five are associated with the type I-F1 system (**Figure 1A**). In total, four of the six CRISPR arrays (one type I-C array and three type I-F1 arrays) encode 24 self-targeting spacers directed to the chromosome or one of the three plasmid of *X. albilineans*. Spacers are expected to guide their associated system to complementary targets resulting in target-degradation during the interference step of the CRISPR-Cas immunity, which is performed in two steps in type I CRISPR-Cas systems. In the first step, Cascade (CRISPR-associated complex for antiviral defense), consisting of three to five Cas proteins and the mature crRNA, binds to the target DNA (31). In the second step, the endonuclease Cas3 is recruited to the target bound by the Cascade complex (32) and nicks the non-target strand followed by degradation of the DNA in a 3'-to-5' direction (33). Our previous work showed that both systems from *X. albilineans* efficiently carried out both steps of type I interference (34).

One measure to evade lethal self-targeting if *cas* genes are functionally encoded is preventing expression of all or some *cas* genes. Therefore, we performed RNA sequencing (RNA-Seq) analysis. We could detect transcripts for all 13 *cas* genes (**Figures 1B** and **S1**), with expression levels ranging between 7 TPM (transcripts per million) for type I-F1 *cas2-3* and 910 TPM for type I-C *cas5*. To compare these values to genes that should be decently expressed, we depicted ten genes that were found to be essential in a member of the *Xanthomonas* species and exhibit TPM levels comparable to the I-C and I-F1 *cas* genes (35) (**Figure S1**). Thus, *X. albilineans* does not appear to protect against lethal self-targeting by actively suppressing transcription of the *cas* genes.

Correct processing of pre-crRNAs to mature crRNAs would be another indication of functional expression of Cas proteins as Cascade proteins are required for processing of crRNAs and the stability of mature crRNAs (36). To examine crRNA processing, we performed RNA-Seq analysis on shorter-length RNAs (**Figure 1C**). Most spacers in the CRISPR arrays gave rise to the expected mature crRNAs for either system with few exceptions (**Figures 1C** and **S1**) (5). Array 4, the type I-C associated array, generally resulted in the expected 11-nt 5' handle (**Figures 1C** and **S1**) and array 2, array 3 and array 6 showed the expected processing pattern of type I-F systems (8-nt 5' handle) (**Figures 1C** and **S1**) (5). Interestingly, in array 2, array 4 and array 6 the most abundant crRNAs were self-targeting crRNAs (**Figure 1C**), excluding the possibility of preventing autoimmunity by solely expression of crRNAs targeting

foreign DNA. Therefore, we conclude that mature crRNAs as well as the necessary Cas proteins are produced.

Figure 1: RNA-Seq analysis reveals transcription of *cas* genes and crRNA biogenesis for the two CRISPR-Cas systems in *Xanthomonas albilineans*. (A) Overview of the type I-C and type I-F1 CRISPR-Cas systems endogenous to *X. albilineans*. *cas* genes associated with the I-C system and the I-F1 system are shown in different shades of blue and pink, respectively. Spacers complementary to a region in the chromosome of *X. albilineans* or one of its plasmids are shown in yellow, and spacers without complementarity are depicted in black. (B) Mapped reads of the type I-C and I-F1 *cas* genes following total RNA-Seq. (C) Mapped reads of the mature crRNAs following small RNA-Seq of shorter-length RNAs. Expected processing patterns are indicated with dashed lines.

Both CRISPR-Cas systems bind and degrade target DNA in *E. coli*

Beyond *cas* expression and crRNA processing, we investigated interference as the last step of CRISPR-Cas immunity. While interference could not be assessed in *X. albilineans* due to

issues with plasmid transformation, our prior testing of Cascade and Cas3 with cell-free transcription-translation (TXTL) systems suggested that both CRISPR-Cas systems could enact interference in isolation (34). To assess if interference activity could lead to lethal chromosomal degradation, we assessed DNA targeting by either system in *E. coli*.

Figure 2: The type I-C and I-F1 CRISPR-Cas systems from *X. albilineans* bind and degrade target DNA in *E. coli*. (A) Overview of the DNA binding assay in *E. coli*. Cascade (orange) is guided by its crRNA to the target region (blue) on the deGFP-reporter plasmid complementary to the spacer (blue). Cascade binding to its target covering the promoter of *degfp* inhibits deGFP expression that can be measured by flow cytometry. The experimental setup lacking a CRISPR array (no array) serves as a negative control. (B) DNA binding by Cascade from both *X. albilineans* systems in *E. coli*. (C) Overview of the DNA degradation assay in *E. coli*. Cascade (orange) is guided by its crRNA to the target region (blue) within the promoter or the coding region of *lacZ* on the *E. coli* chromosome (target locations are shown in D) and recruits Cas3 (red). CRISPR-Cas interference causes DNA degradation which reduces the colony count on agar plates (gray). The experimental setups lacking a CRISPR array (no array) or lacking Cas3 serve as negative controls. (D) DNA degradation by Cascade and Cas3 from both *X. albilineans* systems in *E. coli*.

Fold-reduction in B and D is calculated based on a no-array control that is missing a spacer complementary to the *E. coli* genome or the reporter plasmid. The no-array control is the reference for statistical analyses. Bars indicate the mean of triplicate independent experiments. ***: $p < 0.001$. **: $p < 0.01$. *: $p < 0.05$. ns: $p > 0.05$.

As Cascade must bind its DNA target before recruiting the nuclease Cas3 to induce target degradation (32), we first assessed target binding by Cascade. We encoded the associated genes forming Cascade for the I-C system (*cas5*, *cas8c* and *cas7*) or the I-F1 system (*cas8f1*, *cas5f1*, *cas7f1* and *cas6f*) as an operon on a plasmid under a constitutive promoter. The same

plasmid also encoded a constitutively expressed single-spacer array we used in a previous study to target the deGFP-reporter plasmid (34). The targets in the promoter of *degfp* were flanked by a 5' TTC (I-C system) or 5' CC PAM (I-F1 system), which we previously identified and validated as strong PAMs *in vitro* (34). Finally, the targeted deGFP-reporter plasmid was added, and deGFP production was measured (**Figure 2A**). Cascade of both CRISPR-Cas systems repressed deGFP expression by ~700-fold (I-C system) and ~25-fold (I-F1 system) (**Figure 2B**). Therefore, either system's Cascade can bind DNA targets *in vivo*.

As target-binding was successfully performed by the I-C and the I-F1 Cascade, we proceeded to test targeted DNA degradation by Cas3. We exchanged the deGFP-reporter plasmid with a plasmid encoding the I-C *cas3* or the I-F1 *cas2-3*. We then tested three different spacers targeting the promoter or the coding region of *lacZ* with a flanking 5' TTC (I-C system) or 5' CC (I-F1 system) PAM (**Figures 2C and D**). Both CRISPR-Cas systems significantly reduced plasmid transformation compared to the no-array control, indicating chromosomal degradation and cell death (**Figures 2C and D**). All three spacers of the type I-C system similarly reduced plasmid transformation, whereas spacer 2 and spacer 3 exhibited a ~80-100 times higher fold change than spacer 1 in the type I-F1 system (**Figure 2D**). As expected, the absence of Cas3 did not significantly reduce plasmid transformation in both systems (**Figure 2D**). Given the lethality of chromosomal targeting with Cascade and Cas3 from either system, additional factors likely exist that protect the *X. albilineans* from lethal self-targeting.

Predicted anti-CRISPR proteins inhibit both CRISPR-Cas systems in TXTL

We hypothesized that lethal self-targeting by both CRISPR-Cas systems is inhibited by the presence of Acrs encoded within the *X. albilineans* genome (37, 38). Acrs present in bacteria are often encoded in prophage regions (37). Therefore, we searched for prophage regions in the genome of *X. albilineans* using three different phage prediction tools (39–42). This search revealed 15 prophage regions in six different chromosomal locations (**Figure 3A and Table S1**). Using hidden markov models to identify small proteins encoded in prophage regions next to an HTH-motif containing protein, we identified 17 Acr candidates (initially named Acr_1 through Acr_17) (**Figure 3A and Table S2**). The RNA-Seq analyses indicated that a subset of the predicted Acrs is expressed in *X. albilineans*, suggesting at least some of the Acr candidates might actively inhibit one or both CRISPR-Cas systems (**Table S2**).

Figure 3: Putative Acrs inhibit DNA binding or DNA degradation via either *X. albilineans* CRISPR-Cas system in TXTL. (A) Overview of the genomic organization of CRISPR-Cas systems, putative Acrs and predicted prophages regions in *X. albilineans*. The numbering of the arrays corresponds to those in Figure 1. Placement of the arrays, Acr candidates and self-targets indicates whether they are encoded on the top or bottom strand of the chromosome or plasmid. Prophage regions are predicted with VirSorter v1.0.3 (39), Prophage Hunter (40) and PHASTER (41, 42). Amino-acid sequences of all Acr candidates and their genomic location in *X. albilineans* can be found in Table S2. (B) Overview of testing Acr candidates for their binding and degradation inhibition in TXTL. On the left side, inhibition of binding activity is tested. Inhibition of Cascade-mediated transcriptional repression of deGFP expression indicates a functional Acr. On the right side, inhibition of degradation activity is assessed. Inhibition of DNA degradation by Cas3 recruited by Cascade indicates a functional Acr. Inhibition of DNA degradation while allowing Cascade-mediated DNA-binding classifies an Acrs as degradation-inhibiting Acr. (C) Inhibitory activity of putative Acrs in TXTL. Inhibitory activity of Acr candidates was tested in triplicates and the mean inhibitory activity is depicted.

We first subjected the predicted Acrs to TXTL assays we used previously (43) to assess their inhibitory activity. TXTL assays involve adding DNA constructs, resulting in the production of the encoded RNAs and proteins whose activity can be evaluated in the same reaction. We specifically developed two assays to evaluate the extent to which the inhibitory activity of each predicted Acr acted on or upstream of DNA binding, or on or upstream of DNA degradation (Figure 3B). The first assay assesses inhibition of Cascade-mediated transcriptional

repression of deGFP expression. Active Acrs prevent binding of Cascade to a target in the *degfp* promoter enabling unhindered deGFP expression. The second assay assesses inhibition of DNA degradation by Cas3 recruited by Cascade. Here, a target upstream of the *degfp* promoter is chosen such that active Acrs prevent plasmid degradation. Inhibitory activity in both assays would indicate an inhibitory mechanism at or upstream of DNA binding, while inhibitory activity in only the second assay would indicate a degradation-inhibiting mechanism.

We tested all 17 putative Acrs with both assays for their activity against the type I-C and the I-F1 CRISPR-Cas systems (**Figure 3C**). Transcriptional repression of *degfp* by the I-C Cascade is not inhibited by any tested Acr candidate, at least not with an inhibitory activity higher than 11%. Type I-C degradation on the other hand was repressed by multiple Acr candidates, with Acr_1, Acr_3, Acr_5 and Acr_7 exhibiting the highest inhibitory activities ranging from 30% (Acr_1) to 57% (Acr_3). Acr_1 fully inhibited degradation by the I-F1 Cas3 but not binding by the I-F1 Cascade and thus can be categorized as a DNA degradation-inhibiting Acr. Acr_15 inhibited repression of deGFP expression in the type I-F1 binding assay by ~30%, although no inhibition was observed in the degradation assay. Overall, our TXTL approach identified Acr_1, Acr_3, Acr_5 and Acr_7 as potential type I-C Acrs, and Acr_1 and Acr_15 as potential type I-F1 Acrs.

Acr_3 and Acr_1 inhibit DNA degradation by the I-C and I-F1 Cas3, respectively, in *E. coli*

Given the fact that Acr_1, Acr_3, Acr_5, Acr_7 and Acr_15 exhibited measurable inhibitory activity in TXTL, we next tested these putative Acrs in *E. coli*. Inhibition of DNA binding by Cascade was investigated by adding each Acr candidate to the DNA binding assay and measuring the Acrs' activity in inhibiting transcriptional repression of deGFP (**Figure 4A**). Acr_3 significantly but modestly reduced deGFP fold-repression by the I-C Cascade (**Figure 4B**). All other tested Acr candidates did not significantly reduce deGFP fold-repression for the I-C or the I-F1 Cascade. The lack of binding-inhibition in *E. coli* was expected for Acr_1, Acr_3, Acr_5 and Acr_7 given our prior TXTL results.

As Cascade bound to target DNA recruits Cas3 to induce DNA degradation, we next assess the inhibitory activity of each Acr candidate in the *E. coli* DNA degradation assay (**Figure 4C**). Thereby, inhibition of Cas3-mediated chromosomal DNA degradation results in elevated colony numbers. Similar to our previous *in vitro* experiments, inhibition of a CRISPR-Cas system in the DNA degradation assay but lacking restorage of deGFP expression in the binding assay categorized the Acr as a degradation-inhibiting Acr. Acr_3 and Acr_1 significantly reduced transformation fold-reduction of the type I-C and type I-F1 system, respectively, compared to a -Acr control (**Figure 4D**). Mirroring our TXTL results, Acr_3

inhibited DNA degradation by 60%, while Acr_1 inhibited DNA degradation by 70% (**Figure 4D**). Furthermore, Acr_15 modestly but significantly reduced plasmid transformation of the I-C Cas3 (17-fold reduction of plasmid transformation compared to 71-fold reduction in the -Acr control), leaving open the question whether Acr_15 represents a bona fide Acr. All other Acr candidates did not suppress degradation of one or both CRISPR-Cas systems.

Figure 4: Acr_1 (AcrIF12_{Xal}) and Acr_3 (AcrIC11) inhibit DNA degradation but not DNA binding via either *X. albilineans* CRISPR-Cas system in *E. coli*. (A) Overview of testing putative Acrs for inhibition of transcriptional repression by Cascade in *E. coli*. Acrs actively inhibiting any step upstream of and including Cascade binding to its target restore deGFP expression. See **Figure 2A** for more details. (B) Inhibitory activity of putative Acrs on Cascade-binding in *E. coli*. deGFP repression was measured with flow cytometry. Bars represent the average of three biological replicates. (C) Overview of testing putative Acrs for inhibition of DNA degradation in *E. coli*. Acrs actively inhibiting any step upstream of and including Cas3-mediated DNA degradation restore transformation efficiency. See **Figure 2C** for more details. Type I-C spacer 2 and type I-F1 spacer 3 were used here. (D) Inhibitory activity of putative Acrs on Cas3-mediated DNA degradation in *E. coli*. Fold-reduction in B and D is calculated based on a no-array control that is missing a spacer complementary to the *E. coli* genome or the reporter plasmid. The -Acr control is the reference for statistical analyses. Bars in B indicate the mean of biological triplicates and bars D indicate the mean of biological triplicates carried out with technical triplicates. Data points in B represent biological independent experiments and data points in D represent the mean of technical triplicates of a biologically independent sample. ***: $p < 0.001$. **: $p < 0.01$. *: $p < 0.05$. ns: $p > 0.05$.

After validating the inhibitory activity of Acr_3 and Acr_1 in TXTL and *E. coli*, we asked how both Acrs are related to formerly identified Acrs. Acr_3 does not share high amino-acid similarity to any previously characterized Acr and thus, we renamed Acr_3, following the common nomenclature, to AcrIC11. Acr_1 exhibits a 44.8% amino-acid identity with the previously published AcrIF12 (24) (**Figure S2A**), therefore, we renamed Acr_1 to AcrIF12_{Xal}. AcrIF12 was discovered next to an anti-CRISPR-associated gene 4 (*aca4*) by the “guilt-by-association” method in *Pseudomonas aeruginosa* (24). The mechanism of AcrIF12 is unknown, it is solely reported that this Acrs does not strongly bind to Cascade or Cas3 in isolation (44). To test, if AcrIF12 is also active against the *X. albilineans* type I-F1 system, we subjected AcrIF12 to our degradation-assay in TXTL (**Figures 3B** and **S2B**). AcrIF3, which was previously shown to inhibit type I-F degradation in *P. aeruginosa* (45–48), did not show activity against the type I-F1 system of *X. albilineans* in our assay (**Figure S2B**). AcrIF12 yielded an inhibitory activity of ~30%. Interestingly, the inhibitory activity of AcrIF12 was consistent with all three tested Acr plasmid concentrations and the same phenomenon was observed with AcrIF12_{Xal} (**Figure S2B**). We wondered if AcrIC11 will give similar results and what the range of AcrIF12_{Xal}'s consistent inhibitory activity is. The inhibitory activity of AcrIC11 dropped already from 57% to 11% by using half the amount of Acr plasmid, whereas AcrIF12_{Xal} only dropped from ~100% to 80% when diluting the Acr plasmid 500-fold (**Figure S2C**). Such inhibitory activities over a wide range of Acr concentrations have been associated with catalytic Acrs (44, 49, 50).

Discussion

In this study, we identified two degradation-inhibiting Acrs endogenous to *X. albilineans*, which we named AcrIC11 and AcrIF12_{Xal}. By blocking DNA degradation by Cas3, both Acrs are expected to prevent lethal self-targeting by the two CRISPR-Cas systems in *X. albilineans*. The possibility also remains that additional Cascade-inhibiting Acrs are encoded in the genome of *X. albilineans*. AcrIC11 and AcrIF12_{Xal} add to a growing number of Acrs that inhibit Cas3 but not Cascade by two general mechanisms (24, 45–48, 51–56). AcrIF3 and AcrIE1 directly bind Cas3, while AcrIC3 is suggested to do the same (45–47, 51, 53). In contrast, AcrIE2 and AcrIF5 bind Cascade and likely block Cas3 recruitment while preserving Cascade-induced DNA-binding (55, 56). The mechanisms employed by AcrIC1, AcrIF16 and AcrIF17 to block DNA degradation remain unknown.

Elucidating the exact mechanisms by which AcrIC11 and AcrIF12_{Xal} inhibit DNA degradation could reveal new mechanisms of action. In particular, the inhibitory mechanism of AcrIF12_{Xal} and its homolog AcrIF12 likely differs from already known type I degradation-inhibiting mechanisms based on two observations. First, AcrIF12 did not co-elute with Cascade

nor Cas3 *in vitro* in a previous study (44), ruling out direct binding with either. Second, we showed that AcrIF12_{Xal} maintained its inhibitory activity even when diluted (**Figure S2C**), suggesting that AcrIF12_{Xal} and AcrIF12 could function as multi-turnover proteins. Elucidating the inhibitory mechanism of AcrIF12_{Xal} and AcrIF12 therefore could reveal unique means by which Acrs inhibit Cas3-mediated DNA degradation.

Inhibition of DNA degradation by AcrIC11 and AcrIF12_{Xal} still allows for DNA binding and bears the potential to transform each respective CRISPR-Cas system into a gene regulator. By silencing deGFP expression, we demonstrated that Cascade-mediated gene repression is possible even when AcrIC11 or AcrIF12_{Xal} are present (**Figure 2B**). Gene regulation by self-targeting spacers can be beneficial as was shown previously in *Francisella novicida* which utilize scaRNAs (small CRISPR/Cas-associated RNAs) to facilitate immune escape during host invasion (28). Interestingly, of the six most highly expressed self-targeting crRNAs (array 2: spacer 1; array 4: spacer 1, spacers 28-30; array 6: spacer 4), five are complementary to regions within the first predicted prophage (**Figures 1C and 3A**, see (34) for spacer targets). Array 4: spacer 29 is complementary to a genomic region not associated with a prophage, but is expected to not lead to type I-C targeting as the spacer exhibits 9 mismatches to the target region and the flanking PAM (GGG) was shown to be non-functional (34). The remaining five highly expressed spacers target a putative n6 adenine-specific DNA methyltransferase protein (XALC_0178), two hypothetical proteins (XALC_0182 and XALC_0183), a hypothetical secreted protein (XALC_0189), a hypothetical phage-related protein (XALC_0224) and a putative phage integrase protein (XALC_0242) (57). Cascade-mediated binding to the coding regions of these genes might reduce their expression and could contribute to a stable lysogenic form of the prophage (15).

The genomic location of AcrIC11 and AcrIF12_{Xal} provides hints about the history of *X. albilineans*. AcrIF12_{Xal} is encoded in the first predicted prophage that does also harbor many self-targets (16 in total). The location of AcrIF12_{Xal} would suggest that AcrIF12_{Xal} facilitated prophage integration by hindering DNA degradation by the type I-F1 system. In contrast, AcrIC11 is encoded on plasmid II that does not harbor any self-targets. We suspect that plasmid II was present in *X. albilineans* before integration of the AcrIF12_{Xal}-bearing prophage, as the prophage contains multiple targets of the I-C system that would be blocked by the action of AcrIC11. Self-targeting spacers could also be acquired after prophage integration, although this seems unlikely given that many self-targeting spacers are located at the 3' end of their respective CRISPR arrays (58). Overall, elucidating the order of events could shed light on how prokaryotes come to possess self-targeting spacers and the impact on the evolutionary trajectory of each microorganism.

Material and methods

Plasmid construction

pXalb_IC_Cascade_GG was produced by Gibson Assembly (GA) using pXalb_IC_Cascade (34) as backbone and adding two type I-C repeats interspaced by *mrfp1* that can be excised with the restriction enzyme SapI. J23108 was used as a promoter driving array expression. pXalb_IC_Cascade_sp1-4 were produced with GoldenGate using pXalb_IC_Cascade_GG as backbone and SapI (NEB) as restriction enzyme. Inserts were ordered from IDT as single-stranded oligos, phosphorylated by T4 PNK (NEB) and annealed by heating to 95°C for 5 min and gradually cooling to room temperature.

pXalb_IF1_Cascade_sp1 was created by GA using pXalb_IF1_Cascade (34) as backbone and adding two type I-F1 repeats interspaced by spacer 1. J23108 was used as a promoter driving array expression. pXalb_IF1_Cascade_sp2-4 were created by Site Directed Mutagenesis (SDM) on pXalb_IF1_Cascade_sp1. pXalb_IC_Cascade_NT and pXalb_IF1_Cascade_NT were created by SDM on pXalb_IC_Cascade_GG and pXalb_IF1_Cascade_sp1, respectively. pXalb_IC_Cas3_J23105 and pXalb_IF1_Cas2-3_J23105 were created by GA using pXalb_IC_Cas3 and pXalb_IF1_Cas2-3 (34) for nuclease amplification and pCB705 (43) as backbone, and changing kanamycin resistance to ampicillin resistance. pXalb_noCas3 was produced with SDM on pXalb_IC_Cas3_J23105. p70a_deGFP_sc101 was created by changing the origin of replication (*ori*) of p70a_deGFP to sc101 with GA using pCB705 (43) as source for the *ori*.

pAcr_1-17_T7, pAcrIF12_T7 and pAcrIF3_T7 were created by GA using pET28a as backbone and double stranded DNA fragments containing *E. coli* codon optimized Acr sequences ordered from IDT as inserts. pAcr_1/3/5/7_J23105 and pAcr_15_J23115 were created by SDM on pAcr_1/3/5/7/15_T7, respectively.

All constructed plasmids were verified with Sanger sequencing and can be found in **Table S3**.

RNA-sequencing

X. albilineans CFBP7063 was grown in TSB medium to an OD₆₀₀ of 1.0 and 2 mL were pelleted. Total RNA was extracted with Direct-zol RNA Miniprep Plus (Zymo Research) including the in-column DNase I treatment according to manufacturer's instructions. An additional DNase I treatment with TURBO DNA-free Kit (Thermo Fisher) was performed and the RNA was cleaned with RNA Clean & Concentrator (Zymo Research). The RNA sample was split into two parts, where one part was used for sequencing of total RNA and the second part was used to sequence shorter-length RNAs.

For total RNA-sequencing, ribosomal RNA was depleted and library was prepared using NEBNext Ultra II Directional RNA Library Preparation Kit (NEB). Next-generation sequencing was performed with 50 bp paired-end reads with 25 million reads on an Illumina NovaSeq 6000 sequencer. Sequencing quality was assessed with FastQC (<https://www.bioinformatics.babraham.ac.uk/projects/fastqc/>) and sequencing data was cleaned with Cutadapt (60). Reads were mapped to the *X. albilineans* CFBP7063 genome (FP565176.1) using RNA STAR (61) and visualized with Geneious Prime 2019.1.3 (<https://www.geneious.com>). Htseq-count (62) was used to determine the amount of reads per gene for calculation of TPM.

For RNA-sequencing of shorter-length RNAs, the cleaned RNA was treated with 2 U/μL T4 PNK (NEB) in 1x T4 DNA Ligase Reaction Buffer (NEB) and 1 U/μL SUPERase•In RNase Inhibitor (Thermo Fisher) for 40 min at 37°C. An additional clean up with RNA Clean & Concentrator (Zymo Research) was added. RNAs with a length of 15-100 nts were selected and the library was prepared using NEBNext Small RNA Library Preparation Kit (NEB). Next-generation sequencing was performed with 150 bp paired-end reads with 30 million reads on an Illumina NovaSeq 6000 sequencer. Sequencing quality was assessed with FastQC (<https://www.bioinformatics.babraham.ac.uk/projects/fastqc/>) and sequencing data was cleaned with Cutadapt (60). Bowtie2 (63, 64) was used to align sequencing data to *X. albilineans* CFBP7063 genome (FP565176.1) and Geneious Prime 2019.1.3 (<https://www.geneious.com>) was used to visualize the alignment.

Total RNA-Seq and small RNA-Seq were performed in biological duplicates.

Cascade binding assay in *E. coli*

To assess the binding ability of the type I-C CRISPR-Cas system, *E. coli* MG1655 containing p70a_deGFP_sc101 and pXalb_IC_Cascade_s4 or pXalb_IC_Cascade_NT were used. *E. coli* MG1655 with pXalb_IC_Cascade_s4 only were used as negative control. To determine binding ability of type I-F1 CRISPR-Cas system, *E. coli* MG1655 containing p70a_deGFP_sc101 and pXalb_IF1_Cascade_s4 or pXalb_IF1_Cascade_NT were used. *E. coli* MG1655 with pXalb_IF1_Cascade_s4 only were used as negative control.

Cells were grown in appropriate selection medium at 37°C for 16 h. After back diluting cells to OD₆₀₀=0.02 cells were grown at 37°C to OD₆₀₀=0.8. Cells were diluted 1:25 in 1xPBS and deGFP fluorescence was measured by flow cytometry using the Accuri C6 Plus analytical flow cytometer (BD Biosciences). Gating on living cells was applied and 30,000 events were measured. Final fluorescence values were calculated by subtracting fluorescence obtained from the negative control. Fold-reduction was calculated by the ratio of no-array over the targeting final fluorescence values. Significance was calculated between the no-array and the

targeting fluorescence values using Welch's t-test. $P > 0.05$ is shown as ns, $P < 0.05$ is shown as *, $P < 0.01$ is shown as ** and $P < 0.001$ is shown as ***.

Cas3 degradation assay in *E. coli*

To assess degradation ability of the type I-C system, electrocompetent *E. coli* MG1655 containing type I-C Cascade and a targeting array (pXalb_IC_Cascade_sp1-3) or a no-array control (pXalb_IC_Cascade_NT) were prepared and electroporated with 50 ng pXalb_IC_Cas3_J23105. 50 ng pXalb_noCas3 were electroporated as a no-nuclease control. After a one hour recovery in SOC medium at 29°C, samples were diluted 1:100 in LB medium with 34 µg/mL chloramphenicol (Cm) and incubated at 29°C for 16 h. Following, 1:5 dilutions series of the cultures were prepared in 1xPBS and 5 µL spot dilutions were plated on LB plates with 34 µg/mL Cm and 100 µg/mL ampicillin (Amp). The plates were incubated at 29°C for 24 h before calculation of colony forming units (CFU) values.

Degradation ability of the type I-F1 system was studied with electrocompetent *E. coli* MG1655 containing the type I-F1 Cascade and a targeting array (pXalb_IF1_Cascade_sp1-3) or a no-array control (pXalb_IF1_Cascade_NT) that are electroporated with 50 ng pXalb_IF1_Cas2-3_J23105. 50 ng pXalb_noCas3 was electroporated as a no-nuclease control. After a one hour recovery in SOC medium at 37°C, samples were diluted 1:100 in LB medium with 34 µg/mL Cm and incubated at 37°C for 16 h. Following, 1:5 dilutions series of the cultures were prepared in 1xPBS and 5 µL spot dilutions were plated on LB plates with 34 µg/mL Cm and 100 µg/mL Amp. The plates were incubated at 37°C for 16 h before calculation of CFU values.

Transformation fold-reduction was calculated by the ratio of non-array CFU values over targeting CFU values. Significance was calculated between the $\log_{10}(\text{CFU})$ values obtained by the no-array samples and the targeting samples using Welch's t-test. $P > 0.05$ is shown as ns, $P < 0.05$ is shown as *, $P < 0.01$ is shown as ** and $P < 0.001$ is shown as ***.

Prophage prediction

Prophage regions in the genome of *X. albilineans* CFBP7063 were predicted using VirSorter v1.0.3 (39), Prophage Hunter (40) and PHASTER (41, 42). Predicted prophage regions are listed in **Table S1**.

Acr prediction

All Acrs were predicted by Scott O. Collins and Omer S. Alkhnbashi.

Acr activity in TXTL Cascade binding assay

The Cas proteins required for Cascade formation that were used in TXTL experiments were encoded on separate plasmids. Therefore, a MasterMix with the required Cas protein encoding plasmids in their stoichiometric amount was prepared beforehand. For the type I-C system, we used a stoichiometry of Cas5₁-Cas8c₁-Cas7₇ and for the type I-F1 system, we used the stoichiometry Cas8f1₁-Cas5f1₁-Cas7f1₆-Cas6f₁.

To test if and to what extent predicted Acrs lead to inhibition of binding activity in TXTL, we further developed our previously used TXTL deGFP repression assays (34). Therefore, we prepared 3 μ L TXTL reactions containing the following: 2.25 μ L myTXTL Sigma 70 Master Mix, 0.2 nM p70a_T7RNAP, 0.5 mM IPTG, 1nM pXalb_IC/IF1_gRNA1/nt, 0.5 nM I-C or I-F1 Cascade MasterMix and 1 nM or 0.125 nM pAcr_X_T7 (1 nM: Acr_1-14 and Acr_16; 0.125 nM: Acr_15 and Acr_17). Acr_15 and Acr_17 were added in lower concentrations to avoid unspecific deGFP-inhibition that we observed at a concentration of 1 nM. Reactions without Acr-containing plasmids were used as “-Acr” controls. The TXTL reactions were incubated in a 96-well V-bottom plate at 29°C for 4 h to ensure the formation of a ribonucleoprotein complex. Furthermore, the incubation time leads to expression of the Acrs and allows for inhibition of first steps during CRISPR-Cas activity. After the incubation time, 1 nM p70a_deGFP reporter plasmid is added to the TXTL mix, the reaction is incubated at 29°C for an additional 16 h and fluorescence endpoints are measured with BioTek Synergy H1 plate reader (BioTek) at 485/528 nm excitation/emission (65). The crRNAs encoded in pXalb_IC/IF1_gRNA1 are designed to target within the *degfp* promoter region 3' of a TTC or a CC PAM for the type I-C or the type I-F1 system, respectively, to ensure active targeting leads to inhibition of deGFP expression. All reactions were prepared with the liquid handling machine Echo525 (Beckman Coulter). Inhibition was calculated with the following equation:

$$\% \text{Inhibition} = 100 * \frac{\frac{\text{deGFP}(t, \text{Acr})}{\text{deGFP}(\text{nt}, \text{Acr})} - \frac{\text{deGFP}(t, -\text{Acr})}{\text{deGFP}(\text{nt}, -\text{Acr})}}{1 - \frac{\text{deGFP}(t, -\text{Acr})}{\text{deGFP}(\text{nt}, -\text{Acr})}}$$

“nt” represent values with a non-targeting spacer and “t” represent values with a targeting spacer.

Acr activity in TXTL Cas3 degradation assay

To test Acrs for their inhibitory activity on type I-C or type I-F1 degradation in TXTL, we extended our previously used degradation assay (34) similar to the above described test to check inhibition of Cascade binding. We shifted the target region from the *degfp* promoter to an upstream sequence (flanked by a 5' TTC or 5' CC PAM for the type I-C and the type I-F1 system, respectively). Cas3 was added to the TXTL reaction to enable degradation of the

reporter plasmid and thereby reduction deGFP production while Cascade binding without degradation would not impair deGFP expression. Inhibition of a CRISPR-Cas system by an Acr in the degradation test but not in the binding test indicates specific inhibition of DNA degradation by the Acr.

For the initial test analyzing Acr₁₋₁₇ 3 μ L TXTL reactions were prepared. The TXTL reactions including type I-C Cas proteins included the following: 2.25 μ L myTXTL Sigma 70 Master Mix, 0.2 nM p70a_T7RNAP, 0.5 mM IPTG, 1 nM pXalb_IC_gRNA2/nt, 0.5 nM pXalb_IC_Cas3, 1 nM I-C Cascade MasterMix and 1 nM or 0.125 nM pAcr_X_T7 (1 nM: Acr₁₋₁₄ and Acr₁₆; 0.125 nM: Acr₁₅ and Acr₁₇). Reactions including type I-F1 Cas proteins were composed of: 2.25 μ L myTXTL Sigma 70 Master Mix, 0.2 nM p70a_T7RNAP, 0.5 mM IPTG, 1 nM pXalb_IF1_gRNA2/nt, 0.25 nM pXalb_IF1_Cas2-3, 0.5 nM I-F1 Cascade MasterMix and 1 nM or 0.125 nM pAcr_X_T7 (1 nM: Acr₁₋₁₄ and Acr₁₆; 0.125 nM: Acr₁₅ and Acr₁₇). TXTL reactions were pre-incubated at 29°C for 4 h. The reporter plasmid p70a_deGFP was added to the reaction to a final concentration of 1 nM and incubated at 29°C for additional 16 h. Fluorescence endpoints are measured with BioTek Synergy H1 plate reader (BioTek) at 485/528 nm excitation/emission (65). All reactions were prepared with the liquid handling machine Echo525 (Beckman Coulter). Inhibition was calculated with the following equation:

$$\% \text{Inhibition} = 100 * \frac{\frac{\text{deGFP}(t, \text{Acr})}{\text{deGFP}(\text{nt}, \text{Acr})} - \frac{\text{deGFP}(t, -\text{Acr})}{\text{deGFP}(\text{nt}, -\text{Acr})}}{1 - \frac{\text{deGFP}(t, -\text{Acr})}{\text{deGFP}(\text{nt}, -\text{Acr})}}$$

“nt” represent values with a non-targeting spacer and “t” represent values with a targeting spacer.

Experiments to assess the inhibitory range of Acr₃ (AcrI11) were performed as described above with final Acr plasmid concentrations (pAcr_{3_T7}) ranging from 1 nM to 0.25 nM. Inhibitory range of Acr₁ (AcrIF12_{xa}) was investigated with 5 μ L TXTL reactions. Thereby, a “homemade TXTL” (66) was used. Type I-F1 Cas proteins, crRNA and Acr₁ were pre-expressed in half the reaction volume. Fresh homemade TXTL including the reporter plasmid was added after the incubation time to prolong activity of the TXTL mix. 2.5 μ L pre-expression reactions contained the following: 0.83 μ L TXTL extract, 1.04 μ L TXTL buffer, 0.4 nM p70a_T7RNAP, 1 mM IPTG, 2 nM pXalb_IF1_gRNA2/nt, 0.5 nM pXalb_IF1_Cas2-3, 2 nM I-F1 Cascade MasterMix and 2 nM - 2⁻⁸ nM pAcr_{1_T7}. TXTL reactions were pre-incubated at 29°C for 4 h. The following 2.5 μ L reaction was added after incubation time: 0.83 μ L TXTL extract, 1.04 μ L TXTL buffer and 2 nM p70a_deGFP. Both reactions combined resulted in final plasmid concentrations of: 0.2 nM p70a_T7RNAP, 0.5 mM IPTG, 1 nM pXalb_IF1_gRNA2/nt, 0.25 nM pXalb_IF1_Cas2-3, 1 nM I-F1 Cascade MasterMix, 1 nM - 2⁻⁹ nM pAcr_{1_T7} and 1

nM p70a_deGFP. The 5 μ L reactions were incubated at 29°C for 14 h. All reactions were prepared by hand.

Reactions comparing the inhibitory activity of Acr_1 (AcrIF12_{Xal}), AcrIF12 and AcrIF3 were performed in 5 μ L TXTL reactions as described above. pAcr_1_T7, pAcrIF12_T7 or pAcrIF3_T7 was added at final concentrations of 4 nM - 1 nM.

Acr activity in *E. coli* Cascade binding assay

To test the inhibition of Cascade binding by Acrs in *E. coli*, we adapted our flow cytometry assay assessing binding ability. *E. coli* MG1655 containing the reporter plasmid p70a_deGFP_sc101, pAcr_1/3/5/7_J23105, pAcr_15_J23115 or pET28a (“-Acr” control) and pXalb_IC_Cascade_s4 or pXalb_IC_Cascade_NT were used to investigate the type I-C system. *E. coli* MG1655 with pXalb_IC_Cascade_s4 only were used as negative control. To determine binding ability of the type I-F1 CRISPR-Cas system, *E. coli* MG1655 containing p70a_deGFP_sc101, pAcr_1/3/5/7_J23105 or pAcr_15_J23115 and pXalb_IF1_Cascade_s4 or pXalb_IF1_Cascade_NT were used. *E. coli* MG1655 with pXalb_IF1_Cascade_s4 only were used as negative control.

Cells were grown in appropriate selection medium at 37°C for 16 h. After back diluting cells to OD₆₀₀=0.02 cells were grown at 37°C to OD₆₀₀=0.8. After cells were diluted 1:25 in 1xPBS, deGFP fluorescence was measured by flow cytometry using the Accuri C6 Plus analytical flow cytometer (BD Biosciences). Gating on living cells was applied and 30,000 events were measured. Final fluorescence values were calculated by subtracting fluorescence obtained from the negative control. deGFP fold-repression was calculated by the ratio of no-array over the targeting final fluorescence values. Significance was calculated between the -Acr samples and the Acr-containing samples using Welch’s t-test. P > 0.05 is shown as ns, P < 0.05 is shown as *, P < 0.01 is shown as ** and P < 0.001 is shown as ***. Inhibition was calculated with the following equation:

$$\% \text{Inhibition} = 100 * \frac{\frac{\text{deGFP(T, Acr)}}{\text{deGFP(NT, Acr)}} - \frac{\text{deGFP(T, -Acr)}}{\text{deGFP(NT, -Acr)}}}{1 - \frac{\text{deGFP(T, -Acr)}}{\text{deGFP(NT, -Acr)}}$$

“NT” represent no-array values and “T” represent targeting final values.

Acr activity in *E. coli* Cas3 degradation assay

To test the activity of Acrs in degradation inhibition in *E. coli*, we adapted our transformation assay assessing degradation ability. For the type I-C system, electrocompetent *E. coli* MG1655 containing type I-C Cascade, a targeting array (pXalb_IC_Cascade_sp2) or a no-array control (pXalb_IC_Cascade_NT), and pAcr_1/3/5/7_J23105, pAcr_15_J23115 or pET28a (“-Acr”

control) were prepared and electroporated with 50 ng pXalb_IC_Cas3_J23105. After a one hour recovery in SOC medium at 29°C, samples were diluted 1:100 in LB medium with 34 µg/mL Cm and 50 µg/mL kanamycin (Kan) and incubated at 29°C for 16 h. Following, 1:5 dilutions series of the cultures were prepared in 1xPBS and 5 µL spot dilutions were plated on LB plates with 34 µg/mL Cm, 50 µg/mL Kan and 100 µg/mL Amp. The plates were incubated at 29°C for 24 h before calculation of CFU values.

Degradation ability of the type I-F1 system was studied with electrocompetent *E. coli* MG1655 containing the type I-F1 Cascade, a targeting array (pXalb_IF1_Cascade_sp3) or a no-array control (pXalb_IF1_Cascade_NT), and pAcr_1/3/5/7_J23105, pAcr_15_J23115 or pET28a (“-Acr” control) that are electroporated with 50 ng pXalb_IF1_Cas2-3_J23105. After a one hour recovery in SOC medium at 37°C, samples were diluted 1:100 in LB medium with 34 µg/mL Cm and 50 µg/mL Kan and incubated at 37°C for 16 h. Following, 1:5 dilutions series of the cultures were prepared and 5 µL spot dilutions were plated on LB plates with 34 µg/mL Cm, 50 µg/mL Kan and 100 µg/mL Amp. The plates were incubated at 37°C for 16 h before calculation of CFU values.

Transformation fold-reduction was calculated by the ratio of no-array over the targeting CFU values. Significance was calculated between the values obtained by the -Acr samples and the Acr-containing samples using Welch’s t-test. P > 0.05 is shown as ns, P < 0.05 is shown as *, P < 0.01 is shown as ** and P < 0.001 is shown as ***. Inhibition was calculated with the following equation:

$$\% \text{Inhibition} = 100 * \frac{\frac{\text{CFU(T, Acr)}}{\text{CFU(NT, Acr)}} - \frac{\text{CFU(T, -Acr)}}{\text{CFU(NT, -Acr)}}}{1 - \frac{\text{CFU(T, -Acr)}}{\text{CFU(NT, -Acr)}}}$$

“NT” represent no-array values and “T” represent targeting final values.

Amino-acid sequence alignment

Acr_1 and AcrIF12 amino-acid sequences were aligned with Clustal-Omega 1.2.4. (67).

Supplementary material

Supplementary figures

Figure S1: RNA-Seq reveals transcription of *X. albilineans* cas genes and crRNA processing. Related to **Figure 1.** (A) Transcripts per million calculated from total RNA-Seq results. TPM of type I-C and type I-F1 cas genes are shown. Right table: essential genes shown for comparison. (B) Representation of processed crRNAs. Expected mature crRNAs for the *X. albilineans* type I-C and type I-F1 arrays are shown. (C) Processing pattern of CRISPR array 1 and array 5. Small RNA-Seq coverage of type I-F1 array 1 and array 5 are shown in blue. Self-targeting spacers are depicted in yellow ovals and non self-targeting spacers are represented in black ovals. Dashed lines display the location of the processing event.

Table S2: Genomic location of putative Acrs and their amino acid sequence. Related to Figure 3 and Figure 4.

Discussion

Studies investigating type I CRISPR-Cas systems are still underrepresented if compared to their prevalence in nature. In this work, new techniques were developed to contribute to closing this gap. The newly developed method PAM-DETECT (PAM DETermination with Enrichment-based Cell-free TXTL) was generated to facilitate investigation of PAM requirements focusing on multi-component CRISPR-Cas systems (105). This TXTL-based assay was used to unravel PAM characteristics of 17 different CRISPR-Cas systems. However, also PAM-DETECT comes with disadvantages. One potential downside of PAM-DETECT is its reliance on target-binding rather than target-degradation and PAM requirements during degradation might differ from those during binding (141). Nevertheless, we also presented a method to investigate target-degradation in TXTL and PAM recognition during degradation can readily be verified (105). Formerly, our group developed a TXTL-based PAM assay that relies on degradation rather than binding (142). However, this assay relies on depletion of functional PAMs - contrasting PAM-DETECT, which relies on enrichment of recognized PAMs - and therefore requires a high sequencing depth to also detect lowly recognized PAMs. Nevertheless, combining both assays would unravel PAMs that enable binding while not allowing for target cleavage. Binding-specific PAMs could be used to reprogram endogenous CRISPR-Cas systems to function as gene regulators without the need to mutate/delete the nuclease or downregulate it. Partial complementary or shortened spacers were also shown to enable gene regulation by impairing target-cleavage (143–145). Yet, every CRISPR-Cas system needs to be evaluated separately as the spacer requirements that allow target-binding but impair target-cleavage might differ in every system.

PAM-DETECT facilitated studying PAM requirements of multi-component systems. Even though solely type I systems were assessed in this work, the assay is also adaptable to other class 1 systems or class 2 systems. As type III systems recognize RNAs (30, 146), their interrogation with PAM-DETECT is restricted. Nevertheless, type III systems do not rely on PAMs to distinguish between self and non-self, therefore PAM assays are not expedient anyway (32). However, the poorly understood type IV systems could be well suited for interrogation with PAM-DETECT. The assay requires lack of nuclease activity and type IV systems - besides type IV-C - are typically nuclease deficient (15). One potential hurdle impeding investigation is that type IV systems might require additional, not yet known accessory proteins that are not present in TXTL. Type II and type V CRISPR-Cas systems represent class 2 systems that are suitable for PAM-DETECT, while investigation of type VI systems is not possible as they recognize RNA sequences (42). Mutations of Cas9 or Cas12 impairing their nuclease activity are necessary due to type II and type V systems engaging one

single protein to bind and cleave their target (37, 147). Herein, type V-K systems represent exceptions as these transposon-associated systems include a naturally inactivated RuvC-like nuclease domain (101, 103, 106). PAM-DETECT is therefore a promising tool to contribute to the fundamental understanding of type V-K CASTs, a recently discovered subgroup of type V CRISPR-Cas systems (15, 103).

We did not assess type V-K CASTs in this work, however PAM-DETECT was used to unravel PAM requirements of three type I CASTs (105). CASTs do not only depend on a CRISPR-Cas system for their function but also employ transposon associated genes. As type I-B CASTs integrate in a CRISPR-dependent or a CRISPR-independent manner, they require many proteins to function. We therefore sought to reconstitute transposition in TXTL. The type I-B2.2 CAST from *Rippkaea orientalis* for instance utilizes eight genes in total- even more than the six genes required for type I-E interference. Cascade is formed by *cas6*, *cas8*, *cas7*, and *cas5*, while *tniQ*, *tnsAB*, *tnsC*, and *tnsD* represent transposon associated genes (102, 105). Due to the high number of required proteins and the fact that high expression of RoCascade proteins turned out to be toxic in *E. coli* (105), utilizing TXTL facilitated investigation of transposition. However, the here established TXTL method exhibited some inconsistencies with results derived from our *in vivo* study in *E. coli* (105). Nevertheless, the TXTL-based method successfully defined transposon ends, uncovered which proteins are involved in CRISPR-dependent and CRISPR-independent transposition, and determined the approximate insertion site. Therefore, we recommend TXTL for an initial determination of transposition requirements that can be more extensively studied *in vivo*.

In addition to CASTs, we harnessed TXTL-based methods to assess self-targeting systems as another non-canonical aspect of CRISPR-Cas systems. Thereby, we investigated two extensively self-targeting systems endogenous to the plant pathogen *Xanthomonas albilineans* (105). PAM-DETECT revealed recognition of nearly all PAMs associated with self-targets in *X. albilineans* and both systems were shown to functionally bind and degrade their targets in TXTL (105) and *E. coli*. Therefore, we sought to understand how the bacterium survives lethal autoimmunity. We identified two Acrs (AcrIC11 and AcrIF12_{Xal}) that inhibit target degradation while preserving Cascade-binding for both CRISPR-Cas systems. Nevertheless, the exact mechanism of how both Acrs achieve inhibition of Cas3-degradation remains to be solved.

As most identified Acr mechanisms rely on direct binding to Cas proteins, probing for a direct binding partner would be the first step to assess the means of AcrIC11. So far, three type I degradation inhibiting Acrs were found to bind to Cas3 and two Acrs were found to bind Cascade, probably blocking Cas3 recruitment (83, 148–152). A homolog of AcrIF12_{Xal} was shown previously to not bind to Cascade or Cas3 in isolation (81), which is why we conclude

that AcrIF12_{Xal}'s inhibitory activity most likely does not rely on binding to a Cas protein. As AcrIF12_{Xal} is active in TXTL even if present in high dilutions, we suspect that AcrIF12_{Xal} is a multi-turnover enzyme (105). The exact stoichiometry, in which this Acr inactivates the type I-F1 system still needs to be assessed *in vitro* to allow for reaction conditions with a defined stoichiometry that are not possible in TXTL. To our knowledge, five enzymatic Acrs have been reported with one being a type I Acr (AcrIF11) (60, 73, 79–81). AcrIF11 ADP-ribosylates Cas8, preventing it from PAM recognition (81) and therefore inhibits not only target degradation but also target binding. Thus, we assume that AcrIF12_{Xal} - if it is an enzymatic Acr - uses a mechanism of action that is distinct from AcrIF11. As the already uncovered means employed by enzymatically active Acrs are diverse (60, 73, 79–81), unraveling the mode of action of a novel enzymatic Acr is challenging. A potential starting point to investigate AcrIF12_{Xal} is to figure out which protein is attacked by the Acr. Therefore, a bacterial two hybrid assay could be employed as this screen detects if two proteins are in close proximity even if they are not directly bound to each other (153, 154). As Cas3 activity relies on interactions with Cas8 (28), it seems probable that an enzymatic activity of AcrIF12_{Xal} would be directed to either Cas3 itself or to Cas8 to prevent activation of Cas3. Subsequently, post-translational modifications of either Cas3 or Cas8 can be assessed with mass spectrometry (155, 156).

Besides the means of AcrIC11 and AcrIF12_{Xal}, the reason for two Cas3 proteins being functionally encoded in *X. albilineans* is still unclear. As maintenance of CRISPR-Cas systems was previously associated with fitness costs (157, 158), it would be expected that permanent inactivation of the CRISPR-Cas nucleases would lead to loss of both *cas3* genes. We therefore suggest, *X. albilineans* might have employed its type I-C and type I-F1 systems for a non-canonical defense mechanism. Sensing of phage-infection by *X. albilineans* could trigger downregulation of AcrIC11 and/or AcrIF12_{Xal} expression which would result in host genome degradation. Both type I CRISPR-Cas systems would act as Abi systems and cell death of the infected bacterium would enable altruistic protection of the bacterial community. Overall, TXTL-based methods were established here that can be used as a starting point to look into alternative functions of CRISPR-Cas including self-targeting spacers and CRISPR-Cas system utilizing transposon. The time-saving investigation of CAST PAM requirements and determination of necessary transposition proteins could furthermore boost the investigation of new CASTs and advance their use as biotechnological tools.

Acknowledgments/Danksagung

This thesis would not be possible without the help and support of many people. Firstly, I want to thank my thesis committee Prof. Chase Beisel, Prof. Cynthia Sharma, Jun. Prof. Neva Caliskan and Prof. Frederik Börnke for the support in the last four years. Special thanks to Chase for giving me the opportunity to do my PhD in the Beisel lab and for supporting my scientific development by enabling conference visits or joining the Cold Spring Harbor Summer Course.

Furthermore, many thanks to everyone from the RSYN lab. It was an interesting journey seeing the lab grow from only five members to more than 20 in such a short time. Thanks for the many fun conversations and the uncountable amounts of cake I enjoyed the last four years. Special thanks to my co-first author Ioannis for support in the weird and frustrating last breaths of our paper. My biggest thanks obviously go to my wonderful friends and office mates from the office that should be renamed from “office on the second floor” to “main office”. Daphne, Elena, Frank, Kathi, and Sandra (I had to choose the alphabetic order as I cannot decide whom to name first), you made my PhD life fun! Thank you for many happy days and all the support and gossip. You also made sure that the social distancing times were not so lonely. Thank you office hams! I hope we can all stay in contact, and I will obviously visit you guys and fill the snack area that helps to ease the many frustrating days that every PhD journey holds ready.

Ein großer Dank geht auch an meine Würzburger Freunde, dich mich seit dem ersten Tag in meinem Studium begleiten. Wir haben uns alle durch unsere Höhen und Tiefen unterstützt, was unsere Freundschaft in den letzten Jahren nochmal vertieft hat. Ich hoffe wir verlieren uns nie aus den Augen, machen unsere jährlichen Treffen in Würzburg wahr und trinken das eine oder andere Gläschen (oder Fläschchen) Wein. Ausdrücklich zu nennen ist dabei mein Partner Julian, der mich immer unterstützt hat, auch wenn ich vielleicht in manchen gestressten Momenten etwas weniger liebenswert war. Du hast die gleiche anstrengende Zeit parallel durchgemacht und hattest trotzdem immer ein offenes Ohr und tröstende Worte.

Natürlich geht auch ein großer Dank an meine Familie. Vielen Dank an meine Mama Michaela und meinen Papa Ferdinand für die unendliche Unterstützung all die Jahre in meinem Studium und darüber hinaus. Ohne euch wäre ich nicht die Person ich die jetzt bin und hätte weniger erreicht. Vielen Dank auch an meine beiden Brüderlein Florian und Hermann, ohne die mein Leben um einiges langweiliger wäre.

Appendix: Curriculum Vitae
