

groups 13 and 14 but do not yet seem to be fully understood.<sup>[2]</sup> We herein present ab initio pseudopotential calculations<sup>[3]</sup> on the structures of fluoro(methyl)plumbanes **1–3** which have the general formula  $(\text{CH}_3)_n\text{PbF}_{4-n}$  ( $n = 1-3$ ), as well as  $(\text{CH}_3)_4\text{Pb}$  and  $\text{PbF}_4$ , and compare their stabilities with those of the corresponding divalent species  $(\text{CH}_3)_2\text{Pb}$ ,  $\text{CH}_3\text{PbF}$ , and  $\text{PbF}_2$ .

The optimized geometries<sup>[3]</sup> of **1–3** are shown in Figure 1. The bond angles in all of these unsymmetrically substituted species deviate significantly from idealized tetrahedral values.<sup>[4]</sup> While the F-Pb-F angles are smaller than  $109.5^\circ$ , the

Fig. 1. SCF-optimized geometries for **1** ( $C_3$  symmetry), **2** ( $C_{2v}$ ), and **3** ( $C_{3v}$ ). All structures have been characterized as minima on the potential energy surface by analysis of the harmonic frequencies.

## The Structure and Stability Trends of Fluoro(methyl)plumbanes\*\*

By Martin Kaupp and Paul von R. Schleyer\*

The dramatic differences in the stability of inorganic and organometallic  $\text{Pb}^{\text{IV}}$  compounds are best exemplified by comparing tetraalkyllead with lead tetrahalides: While  $\text{Et}_4\text{Pb}$ , for example, is a relatively stable compound with (still) considerable industrial use,  $\text{PbCl}_4$  decomposes even at low temperatures.<sup>[1]</sup> On the other hand,  $\text{Et}_2\text{Pb}$  is unknown but  $\text{PbCl}_2$  is perfectly stable. These remarkable differences between inorganic and organometallic compounds are of general importance in the chemistry of the heavy elements in

$\text{C-Pb-C}$  angles are considerably larger. This is most apparent in **2** with its  $\text{C-Pb-C}$  angle of approximately  $135^\circ$ . Similarly, the  $\text{C}_3\text{Pb}$  unit in **1** approaches planarity. These angle distortions have consequences for the polymeric arrangements found in the solid state:  $\text{R}_3\text{PbX}$  and  $\text{R}_2\text{PbX}_2$  compounds (R is an alkyl or aryl group, X an electronegative substituent) usually form chain structures of types **4** and **5**, respectively.<sup>[1b]</sup> Note the almost planar  $\text{PbR}_3$  arrangement in **4** (cf. **1**) and the *trans* orientation of the alkyl groups in **5** (cf. **2**). The calculated  $\text{Pb-C}$  and  $\text{Pb-F}$  bonds shorten when the number of fluorine substituents is increased,<sup>[5]</sup> consistent with the results of calculations on the fluoromethanes and -silanes.<sup>[6]</sup>

Both the distorted bond angles and the contracted bond lengths may be rationalized by hybridization arguments with

nonorthogonal hybrid orbitals.<sup>[6a, 7]</sup> Figure 2 displays the partial atomic charges on lead, the p:s ratio  $n$  of the Pb-sp<sup>n</sup> hybridization of the hybrid orbitals used for Pb-C and Pb-F bonding, and the p:s ratio of the average Pb hybridization (Weinhold et al.'s "natural population/hybridization analysis" (NPA)<sup>[8]</sup> was employed). With increasing fluorine substitution, the positive charge on lead increases, and to the contributions of the p orbitals to the Pb hybrid orbitals and the bonding decrease. The larger contributions of the s orbitals to the bonds lead to the observed bond length contraction. Since the hybrid orbitals directed towards the electronegative fluorine substituents generally exhibit roughly twice as much p character as the hybrids used for Pb-C bonding (Fig. 2), the observed deviations from 109.5° angles follow expectations based on Bent's rule.<sup>[9]</sup>

Fig. 2. p:s Ratio  $n$  of the Pb-sp<sup>n</sup> hybridization (based on "natural population analysis" NPA [7]) and partial atomic charges on lead (NPA [7]) for the homologous series of fluoro(methyl)plumbanes (the average lead NPA hybridization and the p:s ratios of the contributions of the lead hybrid orbitals to the  $\sigma$ -bonding "natural localized MOs" (NLMOs) [7] are given). The differences between the average p:s ratio and the p:s ratio of the lead contributions to the  $\sigma$ -Pb-F bonding NLMOs in PbF<sub>4</sub> are due to small hyperconjugative interactions.

The energies  $\Delta E$  for the 1,1-elimination of F<sub>2</sub>, methyl fluoride, or ethane from these Pb<sup>IV</sup> compounds (to give Pb<sup>II</sup> derivatives) are shown in Figure 3. In general, these reactions become less endothermic or more exothermic as the number of fluorine substituents increases. For example,

Fig. 3. Calculated energies  $\Delta E$  [kcal mol<sup>-1</sup>] for 1,1-elimination reactions (loss of F<sub>2</sub>, C<sub>2</sub>H<sub>6</sub>, or CH<sub>3</sub>F, respectively) of substituted Pb<sup>IV</sup> compounds (CH<sub>3</sub>)<sub>n</sub>PbF<sub>4-n</sub> ( $n = 0-4$ ). These reactions convert Pb<sup>IV</sup> to Pb<sup>II</sup> compounds. The MP4SDTQ single-point calculations at the SCF-optimized geometries [2, 4] (cf. Fig. 1) used the same basis sets employed for the geometry optimizations [2] (the reaction (CH<sub>3</sub>)<sub>4</sub>Pb → (CH<sub>3</sub>)<sub>2</sub>Pb + C<sub>2</sub>H<sub>6</sub> was calculated at the MP4SDQ level).

elimination of CH<sub>3</sub>F from (CH<sub>3</sub>)<sub>3</sub>PbF (1) is *endothermic*, whereas loss of CH<sub>3</sub>F is quite *exothermic* for CH<sub>3</sub>PbF<sub>3</sub> (3). Obviously, the tetravalent lead compounds are destabilized in this sense by electronegative substituents. As a result, the disproportionation reaction 2 (CH<sub>3</sub>)<sub>2</sub>Pb → Pb(3P) + (CH<sub>3</sub>)<sub>4</sub>Pb is exothermic, but the reaction 2 PbF<sub>2</sub> → Pb(3P) + PbF<sub>4</sub> is strongly endothermic.<sup>[10]</sup>

This destabilization of Pb<sup>IV</sup> compounds by electronegative substituents may also be explained by the hybridization. The increasing metal charge contracts the lead 6s orbitals more strongly than the 6p orbitals.<sup>[11]</sup> Thus, the already significant differences in the radial extension of s and p orbitals in compounds of heavy main-group elements<sup>[7]</sup> become even larger. Since efficient hybridization requires the size of the orbitals involved to be similar, electronegative substituents increase the hybridization defects<sup>[7]</sup> (cf. Fig. 2) which leads to less efficient covalent bonding. A possible gain in ionic bonding contributions in the polyhalo compounds most probably is compensated by the increased electrostatic repulsions between the substituents.

In contrast to these Pb<sup>IV</sup> compounds, alkanes and silanes are stabilized by geminal fluorine substitution.<sup>[6]</sup> This was shown to be due to negative hyperconjugation  $n(F) \rightarrow \sigma^*(AH, AF)$  ( $A = C, Si$ ).<sup>[6a]</sup> Due to less favorable orbital overlap, these hyperconjugative interactions which lead to a delocalization of the electron density do not contribute significantly to the stabilization of multiply fluorosubstituted alkylplumbanes. Preliminary calculations on the corresponding parent compounds (H instead of alkyl) with both quasi-relativistic and nonrelativistic lead pseudopotentials indicate that relativistic effects also contribute to the trends discussed here. We will present more detailed analyses of a larger set of such group 14 derivatives in the full paper.
